On the other hand, OC users have a higher risk of chlamydial infections.[8,32,40,47] Progesterone can produce cervical eversion, exposing the endocervical columnar epithelium—the target tissue of CT.[40] Estradiol has been implicated in suppressing the endocervical antibodies necessary for resolution of CT.[40] Animal experimentation finds that estrogen-treated individuals have a higher number of infected cervical cells and a longer duration of infection.[48] Because women are probably not selectively exposed to GC versus CT, OCs are not recommended.

Intrauterine Devices

The IUD has a bad reputation in PID.* This reputation is a carryover from the former Dalkon Shield, which is no longer available. Current IUDs such as the Copper T and the Mirena are generally considered safe. However, the use of an IUD is associated with a slightly increased risk of PID, especially in the first 4 months of use. An IUD allows the colonization of bacteria on its surface while simultaneously reducing local immunologic capacity.[49] If a woman with suspected PID has an IUD, it must be removed 12 to 24 hours after initiation of antibiotic therapy in order to prevent the spread of the infection during its removal.

Barrier Methods

Barrier methods of contraception are excellent choices for the prevention of PID. The condom is preferred to cervical protectors, as with this method the sperm more rarely reach the vaginal vault.

Douching

Haphazard douching is to be avoided because it disturbs the vaginal flora. All forms of douching increase the risk of PID and can cause organisms to ascend into the upper genital tract.

One study compared 100 consecutive patients hospitalized for PID with 762 controls and 119 women suspected of having PID.[50] Current douching (defined as any douching during the previous 2 months) was more common among those with PID than among those in both control groups. Among current douchers, PID was related to the frequency of douching. Those who douched three or more times per month were 3.6 times more likely to develop PID than those who douched less than once per month.

A much larger study surveyed 6984 women older than 18 years of age and found that 32% said they had douched within the previous week; 13% reported regular douching more than once a week.[51]

Intercourse During Menses

Intercourse during menses is not recommended unless a condom is used. GC risk is increased by the loss of the protective cervical mucus plug and by the prevalence of blood, a medium of choice for *Gonococcus*. The endometrium is also thought to offer local protection against bacterial invasion, and it is this layer that is being sloughed off during menses.

Smoking

When 197 women hospitalized for their first PID infection were compared with 667 controls with nongynecologic conditions, it was found that cigarette smokers, compared with women who had never smoked, had an elevated risk of PID of 1.7, and former cigarette smokers had an elevated risk of 2.3. There was no dose-response relationship.[52]

A more rigorous study found similar results. This was a case-controlled population-based study of 131 women between 18 and 40 years of age who were treated for their first episode of PID compared with 294 randomly selected patients from the same health maintenance organization. Current smokers compared with those who had never smoked had an increased risk of PID. Women who smoked 10 or more cigarettes a day had a higher risk than those who smoked less.[53]

Education

A physician should review the signs and symptoms of PID with all sexually active women and encourage any woman to seek counsel if she appears to fit the clinical picture for PID. The diagnosis is

*References 5, 16, 19, 22, 27, 54, 55.

easier to make and the recovery more rapid when treatment is instituted early.

THERAPEUTIC APPROACH

Treatment consists of two phases, both of which are important. The first therapeutic goal is to eliminate all pathogens and normalize the microflora of the adnexa. The second is to rehabilitate the damaged tissues.

Women should avoid intercourse until all signs and symptoms are resolved and their male partners have been examined and treated. In addition, all partners from up to 2 months before the illness should be examined[19] and treated if a diagnosis of PID is made. Increased bed rest must also accompany all forms of treatment.

These therapies are recommended as adjuncts to appropriate antibiotic treatment and immune support, as discussed in Chapter 56.

Diet

All dietary inhibitors of immune function (sugar, alcohol, saturated fats, simple carbohydrates) should be limited during both phases of treatment.

Supplements

- Beta-carotene: 100,000 IU/day for 2 or more months
- Vitamin E: 400 IU/day for 3 months
- Vitamin C: 500 mg four times a day for the first week of treatment and then decreased over 3 days to 250 mg three times a day
- Chlorophyll: 10 mg of fat/oil-soluble four times a day for 1 month
- Bromelain: 250 mg (1800 milk clotting unites [MCU]) four times a day for the first week and three times a day for 6 weeks
- Probiotics supplement: minimum 1 billion CFU per day, consider up to 24 billion CFU per day during antibiotic treatment and for 2 months thereafter

Botanical Medicines

- *H. canadensis*: 500 mg of the solid extract (4:1 or 8% to 12% alkaloid content) three times a day during the acute phase; 250 mg three times a day during recovery
- Vaginal packs: daily during the acute phase until there is adequate clinical and laboratory response. After the acute phase, vaginal packs need to be used three times a week, alternating with chlorophyll douches, for 3 weeks.

Physical Medicine

- Diathermy: pulsed, high-intensity diathermy for 10 minutes over the suprapubic area, 10 minutes over the liver, and 10 minutes in the area of the left adrenal (the right being presumably stimulated with the liver).
- Sitz baths: one to two times/day throughout the acute phase. Contrast sitz baths are given in groups of three alterations of hot to cold. Two separate tubs are necessary during this process. The hot is at 105°F to 115°F, the cold at 55°F to 85°F, with the temperatures dependent on the patient's tolerance. The standard treatment is 3 minutes hot and 30 seconds cold, with this cycle being repeated three times in one sitting. The water level in the hot tub is set 1 inch higher than in the cold. Adequate draping is necessary to prevent chilling. As with all hydrotherapy treatments, one always finishes with the cold.

CHAPTER 198

Peptic Ulcer—Duodenal and Gastric

Michael T. Murray, ND

DIAGNOSTIC SUMMARY

- Epigastric distress 45 to 60 minutes after meals or nocturnal pain; both relieved by food, antacids, or vomiting
- Epigastric tenderness and guarding
- Symptoms chronic and periodic
- Gastric analysis showing acid in all cases, with hypersecretion in about one half the patients with duodenal ulcers
- Ulcer crater or deformity usually occurring at the duodenal bulb (duodenal ulcer) or pylorus (gastric ulcer) on radiography or fiberoptic examination
- Positive test for occult blood in stool

GENERAL CONSIDERATIONS

Peptic ulcer formation occurs in the stomach (gastric ulcer) and the first portion of the small intestine (duodenal ulcer). Duodenal ulcers are more common, with an estimated prevalence of 6% to 12% in the United States. Approximately 10% of the U.S. population have clinical evidence of duodenal ulcer at some time in their life. It is four times more common in men than in women and four to five times more common than clinically evident benign gastric ulcer.

Although symptoms of a peptic ulcer may be absent or quite vague, most peptic ulcers are associated with abdominal discomfort noted 45 to 60 minutes after meals or during the night. In the typical case the pain is described as gnawing, burning, cramplike, aching, or "heartburn." Eating or using antacids usually results in great relief. In the elderly, the presentation of peptic ulcer disease may also be subtle and atypical when compared with that in younger patients, leading to a delay in diagnosis.

Even though duodenal and gastric ulcers occur at different locations, they appear to be the result of similar mechanisms. Specifically, the development of a duodenal or gastric ulcer is due to damage to the protective factors that line the stomach and duodenum.

In the past, the focus has primarily been on the acidic secretions of the stomach as the primary cause of both gastric and duodenal ulcers. However, more recently the focus has been on the bacterium *Helicobacter pylori* and nonsteroidal anti-inflammatory drugs (NSAIDs).

Gastric acid is extremely corrosive, with a pH of 1 to 3. To protect against ulcers, the lining of the stomach and small intestine is protected by a layer of mucin. In addition, the constant renewal of intestinal cells and the secretion of factors that neutralize the acid when it comes in contact with the stomach and intestinal linings also protect against ulcer formation.

Excessive gastric acid output is rarely a factor in gastric ulcers, because in these patients gastric acid output is usually normal or reduced. In contrast, almost one half of patients with duodenal ulcers have increased gastric acid output. This increase may be due to an increase in the number of parietal cells. As a group, patients with duodenal ulcers have twice as many parietal cells as normal controls.

Even with an increase in gastric acid output, under normal circumstances there are enough protective factors to prevent ulcer formation. However, when the integrity of these protective factors is impaired, an ulcer can form. A loss of integrity can be due to *H. pylori,* NSAIDs, alcohol, nutrient deficiency, stress, and many other factors. Of these factors, *H. pylori* and NSAIDs are by far the most significant.

Several chronic diseases have also been associated with an increased risk of developing peptic ulcers. These include Crohn's disease, chronic renal failure, liver cirrhosis, cystic fibrosis, chronic obstructive pulmonary disease, systemic mastocytosis (a condition in which there are too many immune mast cells in the body), and myeloproliferative disorders (polycythemia vera, chronic myelogenous leukemia, agnogenic myeloid metaplasia, and essential thrombocythemia).[1]

Helicobacter pylori

The role of *H. pylori* in peptic ulcer disease has been extensively investigated. It has been shown that 90% to 100% of patients with duodenal ulcers, 70% with gastric ulcers, and about 50% of those above age 50 test positive for *H. pylori*.[2] However, more than 80% of *H. pylori*–infected people never actually develop an ulcer.[3] Although it is has been discovered that certain genotypic strains of *H. pylori* may confer additional cytotoxic risk for gastric pathologies,[4] conflicting information warrants further research.[5,6] The presence of *H. pylori* is determined by testing the level of antibodies to *H. pylori* in the blood or saliva or by culturing material collected during an endoscopy as well as measuring the breath for urea.

Low gastric output as well as low antioxidant content in the gastrointestinal mucosa is thought to predispose to *H. pylori* colonization. This increases gastric pH, thereby setting up a positive feedback scenario and increasing the likelihood for the colonization of the stomach and duodenum with other organisms.[7]

Aspirin and Other Nonsteroidal Antiinflammatory Drugs

Aspirin and other NSAIDs are associated with a significant risk of peptic ulcer. In addition, the combination of NSAID use and smoking is particularly harmful to the ulcer patient.[8] Although most studies documenting the relative frequency of peptic ulcers as a consequence of NSAID use have focused on NSAIDs in the treatment of arthritis and headaches, the risk of gastrointestinal bleeding due to peptic ulcers was recently evaluated for aspirin at daily doses of 300, 150, and 75 mg—doses commonly recommended to prevent heart attacks and strokes.[9]

A study conducted at five test hospitals in England found an increased risk of gastrointestinal bleeding due to peptic ulcer at all dosage levels. However, the dosage of 75 mg/day was associated with 40% less bleeding than 300 mg/day and 30% less bleeding than 150 mg/day. The researchers concluded: "No conventionally used prophylactic aspirin regimen seems free of the risk of peptic ulcer complications."

Although there has been a reduction in ulcers induced by NSAIDs with the development of the selective cyclooxygenase-2 inhibitors (Rofecoxib, Celecoxib) for arthritic conditions, aspirin-induced ulcers continue to remain an ongoing issue owing to the increased use of aspirin for protection against cardiovascular events.[8]

THERAPEUTIC CONSIDERATIONS

Individuals experiencing any symptoms of a peptic ulcer need competent medical care. Peptic ulcer complications such as hemorrhage, perforation, and obstruction represent medical emergencies that require immediate hospitalization.

Obviously the best treatment of a peptic ulcer involves identification of the causative factor and its appropriate elimination.

Lifestyle Factors

Stress and Emotions

Stress is universally believed to be an important factor in the pathogenesis of peptic ulcers. However, this belief is based on uncontrolled observations. The medical literature is controversial, and every substantial attempt to examine this assumption has been fraught with methodologic errors.[10]

This problem is further complicated by the observation that men and women with peptic ulcers appear to have distinctly different psychological profiles. In addition, several studies have shown that the number of stressful life events is not significantly different in peptic ulcer patients as compared with carefully selected, ulcer-free controls. These data suggest that it is not simply the amount of stress but rather the patient's response to it that is the significant factor. A large prospective study of 4000 persons who had no history of peptic ulcer disease revealed that those who perceived more significant stress in their lives were at increased risk for developing peptic ulcers[11] (see Chapter 60 for a more complete discussion).

Psychological factors are probably important in some patients with peptic ulcer disease but not in others. As a group, ulcer patients have been characterized as tending to repress emotions, patients should be encouraged to discover enjoyable outlets of self-expression and emotion.

Smoking

Increased frequency, decreased response to peptic ulcer therapy, and an increased mortality due to peptic ulcers are all related to smoking. Three postulated mechanisms for this association are the following[11]:

- Decreased pancreatic bicarbonate secretion (an important neutralizer of gastric acid)
- Increased reflux of bile salts into the stomach
- Acceleration of gastric emptying into the duodenum

Bile salts are extremely irritating to the stomach and initial portions of the duodenum. Bile salt reflux induced by smoking appears to be the most likely factor responsible for the greater incidence of peptic ulcer among smokers. However, the psychological aspects of smoking are also important, because the chronic anxiety and psychological stress associated with smoking appear to worsen ulcer activity.

Nutritional Factors

Food Allergy

Clinical and experimental evidence points to food allergy as a prime etiologic factor.[12-15] The lesions of peptic ulcers and the Arthus reaction (a local inflammatory response due to deposition of immune complexes in tissues) show the same microanatomic changes.[2] In one study, 98% of patients with radiographic evidence of a peptic ulcer had coexisting lower and upper respiratory tract allergic disease.[14] In another study, 25 of 43 allergic children had x-ray–diagnosed peptic ulcers.[15] Clinically, an elimination diet has been used with great success in treating and preventing recurrent ulcers.[13,14] Food allergy is also consistent with the high recurrence rate of peptic ulcers.

Ironically, many people with peptic ulcers soothe themselves by consuming milk, a highly allergic food. Milk should be avoided on this basis alone. However, there is additional evidence suggesting that milk should be avoided by patients with peptic ulcers; for example, population studies show that the higher the milk consumption, the greater the likelihood of ulcer, and milk significantly increases the production of stomach acid.[16]

Fiber

A diet rich in fiber and low in refined sugar is associated with a reduced rate of duodenal ulcers as compared with a low-fiber diet.[3] The therapeutic use of a high-fiber diet in patients with recently healed duodenal ulcers reduces the recurrence rate by one half.[17] This is probably a result of fiber's ability to delay gastric emptying of the liquid phase, counteracting the rapid movement of this phase into the duodenum, which is normally seen in ulcer patients. Although several fibers often used to supplement the diet (e.g., pectin, guar gum, psyllium) have been shown to produce beneficial effects, a diet rich in plant foods is best.[18,19]

Cabbage

Raw cabbage juice has been well documented as having remarkable success in treating peptic ulcers.[20-22] One liter per day of the fresh juice, taken in divided doses, resulted in total ulcer healing in an average of only 10 days. Further research has shown that the high glutamine content of the juice is probably responsible for the efficacy of cabbage in treating these ulcers. In a double-blind clinical study of 57 patients, 24 using 1.6 g/day of glutamine and the rest using conventional therapy (antacids, antispasmodics, diet, milk, and a bland diet), glutamine proved to be the more effective treatment. One half of the glutamine patients showed complete healing (according to radiographic analysis) within 2 weeks, and 22 of the 24 showed complete relief and healing within 4 weeks.[23] Although the mechanism for these results is not known, it is postulated by the authors to be due to the role of glutamine in the biosynthesis of the hexosamine moiety in certain mucoproteins. This could stimulate mucin synthesis, which would benefit peptic ulcer patients.

In addition, cabbage-family isothiocyanates like sulforaphane (SF) have shown considerable activity against *H. pylori*. In one double-blind study, 48 *H. pylori*–infected patients were randomly assigned to feedings of broccoli sprouts (70 g/day; containing 420 µmol of SF precursor) for 8 weeks or to consumption of an equal weight of alfalfa sprouts (not containing SF) as placebo. Intervention with broccoli sprouts but not with placebo decreased the levels of urease measured by the urea breath test and *H. pylori* stool antigen (both biomarkers of *H. pylori* colonization) and serum pepsinogens I and II (biomarkers of gastric inflammation). Values recovered to their original levels 2 months after treatment was discontinued.[24]

Bismuth Subcitrate

Bismuth is a naturally occurring mineral that can act as an antacid; it also exerts activity against *H. pylori.* The best-known and most widely used bismuth preparation is bismuth subsalicylate (Pepto-Bismol). However, bismuth subcitrate has produced the best results against *H. pylori* and in the treatment of peptic ulcers.[23,25] In the United States, bismuth subcitrate preparations are available through compounding pharmacies (to find a compounding pharmacist in your area, call the International Academy of Compounding Pharmacists at 1-800-927-4227).

A key advantage of bismuth preparations over standard antibiotic approaches to eradicating *H. pylori* is that although the bacteria may develop resistance to various antibiotics, they are unlikely to develop resistance to bismuth. As concerns in the medical community grow regarding the failures of current regimens due to resistance, nonpharmacologic management options are becoming required.[26] In India for example, 80% of isolates from 259 peptic ulcer patients tested have shown resistance to metronidazole.[27]

Although resistance to ciprofloxacin and tetracycline was minimal (1% to 4%) in this study, it is evident from recent medical history that greater resistance to these antibiotics will continue to develop. This makes bismuth a rational treatment choice in order to prevent the further development of recalcitrant strains. The usual dosage for bismuth subcitrate is 240 mg twice daily before meals. For bismuth subsalicylate, the dosage is 500 mg four times daily. Bismuth preparations are extremely safe when taken at prescribed dosages. Bismuth subcitrate may cause a temporary and harmless darkening of the tongue, stool, or both. Bismuth subsalicylate should not be taken by children recovering from the flu, chickenpox, or other viral infections as it may mask the nausea and vomiting associated with Reye syndrome, a rare but serious illness.

Flavonoids

Flavonoids are known to counteract both the production and secretion of histamine, an important factor in ulcer formation. They are generally regarded as antiallergy compounds. The use of these compounds seems particularly indicated owing to the probable allergic etiology of peptic ulcers.

Catechin, via its ability to inhibit histidine decarboxylase, offers antiulcer activity. Experimental studies in guinea pigs and rats have demonstrated that catechin has significant antiulcer activity in various models.[28,29] In a human clinical study, oral administration (1000 mg five times daily) resulted in reduced histamine levels in the gastric tissue (determined by biopsy) of normal patients and those with gastric and duodenal ulcers and acute gastritis.[29] It was also demonstrated that the histamine levels, which significantly increase in patients with urticaria and food allergy after the local application of the antigen to the gastric mucosa, could be decreased by the prior administration of catechin.

In a recent study, several flavonoids were shown to inhibit *H. pylori* in a clear-cut concentration-dependent manner.[30] In addition, unlike antibiotics, the flavonoids were also shown to augment natural defense factors that prevent ulcer formation. The activity of flavone, the most potent flavonoid in the study, was shown to be similar to that of bismuth subcitrate.

Sofalcone—a synthetic derivative of sophoradin, a flavonoid found in *Sophora tonkinensis*, an herb used in traditional Chinese medicine—has shown good results in healing ulcers after the eradication of *H. pylori*.[31,32]

Miscellaneous

Vitamins A and E have been shown to inhibit the development of stress ulcers in rats and are important in maintaining the integrity of the mucosal barrier.[33,34] High-dose vitamin A therapy was shown to be useful in the treatment of chronic gastric ulcers in one clinical trial.[35]

Zinc increases mucin production in vitro and has been shown to have a protective effect on peptic ulcers in animals[36] and a curative effect in humans.[37]

Melatonin has been shown in experimental studies to be successful in mitigating breakdown of the gastric lining and resultant ulcer formation.[38] Because this research has focused more on hypersecretion situations, melatonin may be more applicable for duodenal ulcer conditions, where the acid secretion is generally increased.

Botanical Medicines

Glycyrrhiza Glabra. Licorice has historically been regarded as an excellent medicine for peptic ulcer. However, owing to the known aldosterone-like side effects of glycyrrhizinic acid (GA), a procedure was developed to remove GA from licorice and thus to form deglycyrrhizinated licorice (DGL). The result is a very successful antiulcer agent without any known side effects (see Chapter 96).[7,39-43]

The proposed mechanism of DGL is that it stimulates or accelerates the differentiation of glandular cells as well as mucus formation

and secretion.[39] Clinical studies have demonstrated no significant differences in recurrence rates between cimetidine and DGL drug regimens, and rat and human studies have shown the efficacy of DGL in preventing aspirin-induced ulceration and gastric bleeding.[41-43]

An obvious question related to DGL is: "Does DGL have any effect on *H. pylori*?" The answer appears to be yes, because DGL is composed of several flavonoids that have been shown to inhibit *H. pylori*.[30,44]

It appears that in order to be effective in healing peptic ulcers, DGL must mix with saliva. DGL may promote the release of salivary compounds that stimulate the growth and regeneration of stomach and intestinal cells. DGL in capsule form has not been shown to be effective.

The standard dosage for DGL is two to four 380-mg chewable tablets between or 20 minutes before meals. Taking DGL after meals is associated with poor results. DGL therapy should be continued for at least 8 to 16 weeks after a full therapeutic response.

Mastic (Pistacia Lentiscus). Mastic is a resin obtained from the mastic tree (*Pistacia lentiscus*). In Greece it is known as the "tears of Chios," being traditionally produced on the Greek island of Chios; like other natural resins, it is produced in "tears" or droplets. Originally liquid, it is sun-dried into drops of hard, brittle translucent resin. When chewed, the resin softens and becomes a bright white, opaque gum. The flavor is bitter at first, but after chewing the gum releases a refreshing, slightly piney or cedar flavor.

People in the Mediterranean region have used mastic gum as a medicine for gastrointestinal ailments for several thousand years. Recent studies indicate that it may have benefit in healing peptic ulcers.

In a double-blind clinical trial carried out on 38 patients with symptomatic and endoscopically proved duodenal ulcer, patients were given either mastic gum (1 g daily) or a placebo for 2 weeks. Symptomatic relief was obtained in 16 (80%) patients on mastic gum and 9 (50%) patients on placebo, whereas endoscopically proved healing occurred in 14 (70%) patients on mastic gum and 4 (22%) patients on placebo.[45]

In another study, 52 patients with *H. pylori* infection were randomized to receive either 350 mg three times daily of pure mastic gum for 14 days (group A); 1.05 g three times daily of pure mastic gum (group B) for 14 days; pantoprazole 20 mg twice daily plus pure mastic gum 350 mg three times daily for 14 days (group C); or pantoprazole 20 mg twice daily plus amoxicillin 1g twice daily plus clarithromycin 500 mg twice daily for 10 days (group D). Eradication of *H. pylori* was confirmed in 4 of 13 patients in group A and 5 of 13 in group B. No patient in group C achieved eradication, whereas 10 of 13 patients in group D did. These results confirm that mastic gum has some bactericidal activity on *H. pylori* in vivo but not enough to produce consistent clinical eradication.[46]

Rheum Species. In cases of active intestinal bleeding, rhubarb (*Rheum* species) preparations can be extremely effective. In one double-blind study, three kinds of alcohol-extracted rhubarb tablets were studied (*Rheum officinale Baill*; *Rheum palmatum* L.; *Rheum tanguticum Maxim ex Balf*).[47] Their efficacies in a group of 312 cases of bleeding gastric and duodenal ulcers were 90.7%, 93.7%, and 92.8% respectively. The time taken for the stool occult blood to change from positive to negative was 57.1, 53.4, and 56 hours respectively. The beneficial actions are due to the presence of astringent anthraquinones and flavonoids.

Plantain Banana. In rats, the dried extract of the unripe plantain banana (*Musa sapientum* var. *paradisiaca*) has been found to have antiulcerogenic activity against various experimentally induced ulcers.[48-50] This effect appears to be similar to that of DGL (i.e., stimulation of mucosal cell growth rather than inhibition of gastric acid secretion).

Zingiber Officinale. Ginger root *(Zingiber officinale)* has traditionally been used for the treatment of gastrointestinal ailments such as indigestion, motion sickness, and nausea associated with pregnancy. One study used in vitro experimentation to test a methanol extract of ginger root as an agent against 19 strains of *H. pylori.* Results showed that growth was inhibited against all 19 strains.[51] Although more research is required to characterize the best form of this botanical medicine and to learn of its efficacy in actual patients, given its safety profile and cost effectiveness, it is certainly worth a try.

Artemisia Douglasiana. Growing on the western slopes of the Rockies, *Artemisia douglasiana* has been used as a folk remedy in Argentina to treat gastric ulcers and skin lesions since the late 1960s. *A. douglasiana* and its active constituent dehydroleucodine are known to act as potent antioxidants and, like DGL and plantain, they confer protection to the gastric lining via significantly enhanced mucus secretion.[52,53]

Allium Sativum. People whose diets are high in garlic and onions are well known to have a lower incidence of stomach cancer. *H. pylori* is a risk factor for stomach cancer as well as peptic ulcers, and in vitro studies have demonstrated that garlic does indeed inhibit its growth. Also noteworthy is the report that garlic can be useful for antibiotic-resistant strains as well. The author of this paper points out that human clinical trials are necessary in order to verify the efficacy of this low-cost treatment option.[54]

THERAPEUTIC APPROACH

Peptic ulcer disease should be recognized as a heterogeneous group of disorders with a common final pathway leading to an ulcerative lesion in either the gastric or duodenal mucosa. Patients must be carefully evaluated to determine which of the previously mentioned factors is most relevant to their health problem. This is difficult, however; therefore a more general approach may be necessary.

The first step is to identify and eliminate or reduce all factors implicated in the etiology of peptic ulcers: food allergy, cigarette smoking, stress, and drugs—especially aspirin and other NSAIDS. Once the causative factors have been controlled, attention should be directed at healing the ulcers, inhibiting exacerbating factors (e.g., reducing excess acid secretion if present), and promoting tissue resistance. Finally, the proper diet and lifestyle should be developed to prevent further recurrence.

Peptic ulcer complications—hemorrhage, perforation, and obstruction—represent medical emergencies that require immediate hospitalization.

Psychological Considerations

The physician should assist the patient in developing an effective stress reduction program, eliminating or controlling of stressors, and designing a regular relaxation plan.

Diet

The patient should eliminate allergic food, eat foods high in dietary fiber and low in refined sugars, and eat various members of the cabbage family and garlic.

Supplements

- Vitamin A: 20,000 IU three times a day
- Vitamin C: 500 mg twice a day

- Vitamin E: 100 IU twice a day
- Flavonoids: 500 mg twice a day
- Zinc: 20 mg/day
- Glutamine: 500 mg three times a day
- Bismuth subcitrate: 240 mg twice a day before meals

Botanical Medicines

- Deglycyrrhizinated licorice: 380 to 760 mg three times a day 20 minutes before meals
- Mastic gum: 350 to 1000 mg three times a day

DIAGNOSTIC SUMMARY

- Gingivitis—inflammation of the gingiva characterized by erythema, contour changes, and bleeding
- Periodontitis—localized pain, loose teeth, demonstration of dental pockets, erythema, swelling, or suppuration; possibly also alveolar bone destruction seen on radiograph

GENERAL CONSIDERATIONS

Periodontal disease is an inclusive term used to describe an inflammatory condition of the gingiva (gingivitis) or periodontium (periodontitis) or both. Periodontal disease usually involves a disease process that typically progresses from gingivitis to periodontitis.[1,2] It may be a manifestation of a more systemic condition such as diabetes mellitus, collagen diseases, leukemia or other disorders of leukocyte function, anemia, or vitamin deficiency states.[1] Periodontal disease may also contribute to systemic disease. For example, periodontal disease has been linked to atherosclerosis via an increased level of serum C-reactive protein, a marker for inflammation and a strong risk factor for coronary artery disease.[3]

Because alveolar bone loss may be noninflammatory, our definition of periodontal disease excludes the processes causing only the loss of teeth (the majority of which are due to osteoporosis or endocrine imbalances).[1] These conditions reflect systemic disease, with local factors playing only a minor role; therefore the focus should be on treating the underlying condition rather than the "periodontal disease." In this context, noninflammatory alveolar bone loss should be viewed as a separate entity, since it involves a different etiology (see Chapter 194).

The focus of this chapter is the use of nutrition and lifestyle improvement as an adjunctive therapy to aid in the control and prevention of the causes of inflammatory periodontal disease. This is a good example of a condition that is probably best treated with combined expertise (i.e., a dentist or periodontist and a nutritionally minded physician). Although oral hygiene is of great importance in treating and preventing periodontal disease, it is insufficient in many cases. The host defense must be normalized if development and progression of the disease are to be controlled.[1,4] To a large extent, the nutritional status of the individual determines the status of host defense factors.

Prevalence and Epidemiology

The prevalence of periodontal disease increases directly with age. The rate of periodontal disease is approximately 15% at age 10, 38% at age 20, 46% at age 35, and 54% at age 50. As a group, men have a higher prevalence and severity of periodontal disease than women. Periodontal disease is inversely related to increasing levels of education and income. Rural inhabitants have a higher level of severity and prevalence than their urban counterparts.[1]

Pathophysiology

Understanding the underlying pathophysiology of any disease process leads to a more effective treatment plan. In periodontal disease this involves understanding the normal host protective factors in the periodontium. Page and Schroeder[4] concluded: "Clearly bacteria are essential agents, but their presence is in itself

insufficient; host factors must be involved if the disease is to develop and progress."

Factors involved in host resistance include the following:

- The environment of the gingival sulcus
- Bacterial factors
- Leukocyte function
- Complement activation
- Immunoglobulin (Ig)E and mast cell function
- Amalgam restoration
- Miscellaneous local factors
- The structure and integrity of the collagen matrix of the periodontium and gingiva

Gingival Sulcus

The gingival sulcus, a V-shaped crevice that surrounds each tooth, is bounded by the surface of the tooth on one side and the epithelium lining the free margin of the gingiva on the other. The anatomy of the gingival sulcus is ideal for bacterial growth, because it is resistant to the washing and cleansing action of saliva. Furthermore, the gingival fluid (sulcular fluid) provides a rich nutrient source for microorganisms. The clinical determination of the depth of the gingival sulcus is an important diagnostic parameter. Patients with periodontal disease should be monitored; biannual visits to the dentist should be sufficient in most cases.

Bacterial Factors

Bacterial plaque has long been considered the etiologic agent in most forms of periodontal disease.[1] However, an appreciation of host defense factors has now developed.[1,4] Bacteria are known to produce and secrete numerous compounds that are quite detrimental to the status of the host's defense mechanisms. These compounds include the following[1]:

- Endotoxins and exotoxins
- Free radicals and collagen-destroying enzymes
- Leukotoxins
- Bacterial antigens, waste products, and toxic compounds

Polymorphonuclear Leukocytes

Polymorphonuclear neutrophils (PMNs) constitute a first line of defense against microbial overgrowth. Defects in PMN functions are "catastrophic" to the periodontium.[1,4] PMN functions are depressed in the geriatric population as a whole and in patients with diabetes, Crohn's disease, Chédiak-Higashi syndrome, Down syndrome, and juvenile periodontitis.[1,4] These patients are at extremely high risk for developing rapidly progressing periodontal disease, as are people with transient neutropenia. Transient defects in PMN function may be responsible for the periods of quiescence and exacerbation noted in periodontal disease. In addition to serving a vital role in protecting against periodontal disease, PMNs also play a major role in tissue destruction. PMNs release numerous free radicals, collagenases, hyaluronidases, inflammatory mediators, and an osteoclast stimulator.[1,4]

Macrophages and Monocytes

These leukocytes are found in increased numbers in periodontal disease. They serve to phagocytize bacteria and debris and are the primary source of prostaglandins in the diseased gingiva, releasing large quantities of enzymes believed to play a major role in collagen destruction.[1,4]

Lymphocytes

The major role lymphocytes play in periodontal disease involves lymphokine production. Their role in periodontal disease is overshadowed by the roles of the other immune system components discussed, but lymphokines are involved in promoting PMN and monocyte chemotaxis, fibroblast destruction, and osteoclast activation.[1,4]

Complement

The complement system is composed of at least 22 proteins and accounts for more than 10% of the total serum globulin. On activation, complement components act in a cascade fashion. Complement can be activated via the classic or alternative pathway. The complement system plays a critical role in immunologic and nonspecific resistance to infection and in the pathogenesis of tissue injury. The products of complement activation regulate a number of events, including the release of mediators from mast cells; promotion of smooth muscle contraction; chemotaxis of PMNs, monocytes, and eosinophils; and phagocytosis by immune adherence.[5] The net effect is an increase in gingival permeability, resulting in the increased penetration of bacteria and bacterial by-products and, in essence, the initiation of a positive feedback cycle.[1,4]

Other effects of complement activation include solubilization of immune complexes, cell membrane lysis, neutralization of viruses, and the killing of bacteria.[5] In periodontal disease, activation of complement via the alternative pathway within the periodontal pocket is possibly the major factor in tissue destruction.

Mast Cells and Immunoglobulin E

Mast cell degranulation is also a major factor in periodontal disease. Degranulation results in the release of inflammatory mediators (i.e., histamine, prostaglandins, leukotrienes, kinins, serotonin, heparin, and serine proteases).[1] Mast cell degranulation can be initiated by IgE complexes, complement components, mechanical trauma, endotoxins, and free radicals. The finding of increased IgE concentrations in the gingivae of patients with periodontal disease suggests that allergic reactions may be a factor in the progression of the disease in some patients.[6]

Amalgam Restorations

Faulty dental restorations and prostheses are common causes of gingival inflammation and periodontal destruction.[1] Overhanging margins provide an ideal location for the accumulation of plaque and the multiplication of bacteria. If the restoration is a silver amalgam filling, there may be even more involvement due to decreased activities of antioxidant enzymes. Mercury accumulation results in a depletion of the free radical–scavenging enzymes glutathione peroxidase, superoxide dismutase, and catalase.[7] The proteoglycans and glycosaminoglycans of the collagen matrix are particularly sensitive to free radical damage.[8]

Miscellaneous Local Factors

Numerous local factors favor the progression of periodontal disease; these include the following:

- Food impaction
- Unreplaced missing teeth
- Malocclusion
- Tongue thrusting
- Bruxism
- Toothbrush trauma
- Mouth breathing
- Tobacco (discussed later)

Tobacco and Alcohol

Tobacco smoking is associated with increased susceptibility to severe periodontal disease and tooth loss.[1,9,10] (In fact, tobacco

smoking is associated with increased susceptibility to virtually every major chronic disease.) Many of the harmful effects of tobacco smoking result from free radical damage, particularly to epithelial cells. Furthermore, smoking greatly reduces the levels of ascorbic acid, thereby potentiating its damaging effects.[11] Carotenes and flavonoids have been shown to greatly reduce some of the toxic effects of smoking.[12,13]

In addition to cigarette smoking, there is a dose-dependent association between alcohol consumption and periodontal disease.[14] Presumably the combination of smoking and drinking alcohol produces an even greater negative effect on periodontal health.

Structure and Integrity of the Collagen Matrix

The collagen matrix of the periodontal membrane serves as periosteum to the alveolar bone and enables the dissipation of the tremendous amount of pressure exerted during mastication.[15] The status of the collagen matrix of the periodontium, specifically the extracellular proteoglycans of the gingival epithelium, determines the rate of diffusion and the permeability of inflammatory mediators, bacteria and their by-products, and destructive enzymes from the oral cavity.[16,17] Owing to the high rate of protein turnover in periodontal collagen, the integrity of the collagen matrix in this area is extremely vulnerable to atrophy when the necessary cofactors for collagen synthesis (e.g., protein; vitamins C, B_6 and A; zinc; copper) are absent or deficient.[15]

The collagen of the periodontium is particularly rich in glycosaminoglycans.[15-18] Heparin sulfate, dermatan sulfate, and chondroitin sulfate proteoglycan 4 are the major glycosaminoglycans present. Stabilization of collagen is the major treatment goal (see later).

THERAPEUTIC CONSIDERATIONS

Therapeutic goals in treating periodontal disease from a nutritional perspective follow:

- Decrease wound healing time (because the time span for wound healing is longer in patients who are more susceptible to periodontal disease[19]).
- Improve membrane and collagen integrity.
- Decrease inflammation and free radical damage (inflammation can induce a vicious cycle and promote periodontal disease).
- Enhance immune status (defects in the immune system, particularly PMNs, are catastrophic to the periodontium).

Individual nutrients are discussed later in the context of their roles in achieving these therapeutic goals.

Nutrition

Vitamin C

Vitamin C (ascorbic acid) plays a major role in preventing periodontal disease, as is evident from many experimental studies.[1,20-24] The classic symptom of gingivitis seen in scurvy illustrates the vital function of vitamin C in maintaining the integrity of membrane and collagen as well as supporting immunocompetence. Deficiency of vitamin C is associated with defective formation and maintenance of collagen, ground substance, and intercellular cement substance in mesenchymal tissue.[1] The deficiency effects on bone include retardation or cessation of osteoid formation, impaired osteoblastic activity, and osteoporosis. Subclinical vitamin C deficiency plays a significant role in periodontal disease via these effects, which also include delayed wound healing.[1,20-24]

Decreased vitamin C levels are also associated with increased permeability of the oral mucosa to endotoxin and bacterial byproducts as well as impaired leukocyte functions (particularly with regard to PMNs). The role vitamin C plays in increasing chemotaxis and phagocytosis by PMNs is best exemplified by its effect on Chédiak-Higashi syndrome. This autosomal recessive trait is associated with compromised PMN and monocyte chemotaxis and phagocytosis, all of which are responsive to vitamin C supplementation.[25] This syndrome is also associated with an extremely rapidly progressing periodontitis.[1,4]

Vitamin C's other effects on immune status include enhancing lymphoproliferative response to mitogens and increasing interferon levels, antibody response, immunoglobulin levels, and the secretion of thymic hormones. Vitamin C also possesses significant antioxidant and antiinflammatory properties and decreases wound healing time.

Vitamin D

Low vitamin D is associated with gingivitis; it is a likely cause of both gingivitis and periodontal disease. In a study that analyzed data from 77,503 gingival units (teeth) in 6700 never smokers ages 13 to 90, those with the highest levels of vitamin D had a 30% decreased incidence of gingivitis. This was found consistent across racial or ethnic groups and was similar among men and women as well as among users and nonusers of vitamin and mineral supplements.[26a] A similar association is found for periodontal disease, in that men in the highest quintile experienced 39% less bone loss, while women experienced 26% less. Supplementation reduces bone loss.[26b] To further strengthen the case for the causal role of vitamin D deficiency, a study found a much higher incidence of the TT VDR (vitamin D receptor) polymorphism and aggressive periodontitis.[26c]

This low vitamin D status likely contributes to the link between periodontal disease and breast cancer in women.[26d]

Sucrose

Sugar is known to significantly increase plaque accumulation while simultaneously decreasing PMN chemotaxis and phagocytosis.[1,27] This inhibition of PMN function is due to osmotic effects and competition with vitamin C.

Vitamin C and glucose are known to compete for intracellular transport sites, with this intracellular transport being largely insulin-dependent. (See Chapter 56 for further information on nutrient factors and immune function.)

Considering the fact that the average American consumes in excess of 175 g/day of sucrose and other refined carbohydrates, it is safe to say that most Americans have a chronically depressed immune status that puts them at increased risk for periodontal disease.[28]

Vitamin A

Vitamin A deficiency predisposes people to periodontal disease. Deficiency of vitamin A is associated with the following[1]:

- Keratinizing metaplasia of the gingival epithelium
- Early karyolysis of gingival epithelial cells
- Inflammatory infiltration and degeneration
- Periodontal pocket formation
- Gingival calculus formation
- Increased susceptibility to infection
- Abnormal alveolar bone formation

Vitamin A is necessary for collagen synthesis and wound healing, maintaining the integrity of epithelial and mucosal surfaces and their secretions, and enhancing numerous immune functions.

Beta-carotene may be a more advantageous supplement owing to its affinity for epithelial tissue and potent antioxidant activity.[13]

Zinc and Copper

Zinc functions synergistically with vitamin A in many metabolic processes.[29] The severity of periodontal disease is positively associated with increased serum copper levels while zinc levels are significantly decreased (i.e., an increased copper-to-zinc ratio).[30] This is consistent with other causes of chronic inflammation and signifies activation of metallothionein, which increases ceruloplasmin formation while increasing zinc sequestration in response to inflammation.[29]

Zinc's importance in treating periodontal disease cannot be overstated. In the United States, marginal zinc deficiency is widespread, particularly in the elderly.[30,31] This may be a factor in the increasing prevalence of periodontal disease with age, although the geriatric population as a whole is at higher risk for development of numerous nutrient deficiencies. The functions of zinc in the gingiva and periodontium include the following[29,31-33]:

- Stabilization of membranes
- Inhibition of calcium influxes
- Antioxidant activity
- A metallocomponent in at least 40 enzymes, including those for DNA, RNA, and collagen synthesis
- Inhibition of plaque growth
- Inhibition of mast cell degranulation
- Numerous immune activities including increased PMN chemotaxis and phagocytosis

Zinc is also known to significantly reduce wound healing time.[26,29]

Zinc's positive effects in established periodontal disease are also due to its action on calcium- and calmodulin-mediated processes such as mast cell degranulation, tissue damage induced by endotoxin, and increased vascular permeability.[29] These calcium-mediated events are responsible for much of the tissue destruction seen in periodontal disease.[34]

Regular (twice daily) use of a mouthwash that contains a 5% zinc solution inhibits plaque growth.[32] However, lower concentrations or less frequent mouth washing are not particularly successful.

Vitamin E and Selenium

These two nutrients function synergistically in antioxidant mechanisms and seem to potentiate each other's effects. Vitamin E alone has been demonstrated to be of considerable value in patients with severe periodontal disease.[1,35] This can largely be attributed to the decreased wound healing time associated with vitamin E.[36] The antioxidant effects of vitamin E are particularly needed if silver amalgam is present. Mercury depletes the tissues of the antioxidant enzymes superoxide dismutase, glutathione peroxidase, and catalase. In animal studies, this toxic effect of mercury is prevented by supplementation with vitamin E.[7] Selenium and vitamin E's antioxidant activities also deter periodontal disease, as the effects of free radicals are extremely damaging to gingival proteoglycans and glycosaminoglycans.[8]

Coenzyme Q_{10}

Ubiquinone, an essential coenzyme involved in mitochondrial oxidative phosphorylation, is also an effective antioxidant.[37,38] Coenzyme Q_{10} (CoQ_{10}) is widely used in Japan for many conditions including periodontal disease. A review of seven studies using CoQ_{10} found that 70% of the 332 patients involved responded favorably to supplementation.[37] A double-blind study comprising 56 subjects found that the supplemented group responded significantly, while the placebo group displayed very little change in periodontal pocket depth and tooth mobility.[38]

Flavonoids

As a group, these compounds are perhaps the most important components of a program to alleviate periodontal disease. Flavonoids are extremely effective in reducing inflammation and stabilizing collagen structures. Flavonoids affect collagen structure by doing the following[39-44]:

- Decreasing membrane permeability, thereby decreasing the load of inflammatory mediators and bacterial products
- Preventing free radical damage with their potent antioxidant properties
- Inhibiting enzymatic cleavage by hyaluronidases and collagenases
- Inhibiting mast cell degranulation
- Cross-linking with collagen fibers directly

The more biologically active flavonoids (e.g., anthocyanidins and proanthocyanidins) should be supplemented, because rutin has little collagen-stabilizing effect. Perhaps the most useful source is grape seed extract, because its proanthocyanidins have been reported to possess a wide range of biological properties that are useful against periodontal disease.[45] In one study in mice, the effects of a grape seed proanthocyanidin extract (GSE) on the production of reactive oxygen species (ROS) and on the protein expression of inducible nitric oxide synthase (iNOS) by murine macrophages stimulated with lipopolysaccharides (LPS) of periodontopathogens was investigated. GSE strongly decreased iNOS and ROS production.[46]

The flavonoid components of *Camellia sinensis* (green tea) have demonstrated not only activity against gingival bacteria but also direct antiinflammatory effects. Epidemiologic studies have shown green tea intake to protect against periodontal disease and tooth loss.[47] Clinical studies have focused on direct local effects with either soft chewable candy or hydroxypropylcellulose strips impregnated with green tea catechin. In the study with the hydroxypropylcellulose strips, the pocket depth and the proportion of pathogenic bacteria were markedly decreased.[48] The study using the soft candy was double-blinded; it indicated by the approximal plaque index (API) and the sulcus bleeding index (SBI) scores that the green tea soft chews significantly reduced plaque and the degree of gingival inflammation.[49] A double-blind study also showed that chewing gum containing procyanidolic oligomers also minimizes gingival bleeding and plaque accumulation.[50]

Folic Acid

The use of folate, either topically or systemically, in double-blind studies produced significant reductions of gingival inflammation as determined by reduction in color changes, bleeding tendency, gingival exudate flow, and plaque scores.[51-55] The folate mouthwash, 0.1% folic acid, is significantly more effective than oral supplementation of either 2 or 5 mg/day, suggesting a local mechanism of action.[53,54] Folate has been demonstrated to bind plaque-derived endotoxin.[53-56] The use of folate mouthwash is particularly indicated for pregnant women and oral contraceptive users as well as for conditions associated with an exaggerated gingival inflammatory response or folate antimetabolites (e.g., phenytoin, methotrexate).[53,54]

Epithelial cells of the cervix and the oral cavity appear to suffer from a similar "end organ" deficiency of folic acid under the

hormonal influences of pregnancy and oral contraceptive use.[54,56,57] The cervical dysplasia associated with oral contraceptive use also responds to pharmacologic doses of folic acid (i.e., 8 to 30 mg/day).[56,57] (Whitehead's work[56] was the inspiration for the use of folic acid by Pack and Thomson[53,54] in the treatment of gingivitis of pregnancy.) The sera and leukocytes of pregnant women and oral contraceptive users contain a macromolecule that binds folate, which, more than malabsorption or decreased intake, appears to be the major factor for end-organ folate deficiency.[58] Double-blind studies have shown that the beneficial effects of folic acid are not limited to women,[49,50,53] and the positive effects are not limited to gingivitis because periodontitis improves as well.[55]

Botanical Medicines

A number of botanical compounds have shown an ability to inhibit plaque formation, but perhaps the most popular botanical medicine in a toothpaste is an alcoholic extract of *Sanguinaria canadensis* (bloodroot). This extract contains a mixture of benzophenanthridine alkaloids, but chiefly sanguinarine is available in commercial toothpastes and mouth rinses. Sanguinarine demonstrates properties useful in preventing the formation of dental plaque. It has broad antimicrobial activity as well as antiinflammatory properties. In vitro studies indicate that the antiplaque action of sanguinaria is due to its ability to inhibit bacterial adherence. Electron microscopic studies of bacteria exposed to sanguinarine demonstrate that bacteria aggregate and become morphologically irregular.[59] Sanguinarine appears to be less effective than chlorhexidine mouthwash, but it is effective in many cases and does have the advantage of being a natural compound versus a synthetic.[59,60]

Another useful botanical medicine in periodontal disease is the triterpenoid extract of *Centella asiatica* (gotu kola). This extract has demonstrated impressive wound healing properties (see Chapter 75). One study demonstrated that *Centella* extract was helpful in speeding up recovery after laser surgery for severe periodontal disease.[61]

THERAPEUTIC APPROACH

As discussed earlier, many factors are involved in the initiation and promotion of periodontal disease. Effective therapy requires that all relevant factors be controlled. Because there are as yet no clear guidelines for determining which factors are most important for a given patient, a general approach is recommended here. All patients who smoke should be helped to stop, because continued smoking greatly decreases the success of any therapy for periodontal disease. Because those factors that increase the risk for osteoporosis (e.g., low calcium and vitamin D, cigarette smoking, etc.) also predispose individuals to the risk for periodontal disease and tooth loss, attention should be directed to Chapter 194 as well as to the recommendations given here.

Hygiene

Patients should visit a dentist periodically, as needed, to eliminate accumulated plaque and calculus. Brushing after meals and daily flossing are necessary.

Diet

A diet high in dietary fiber may have a protective effect via increased salivary secretion.[20] Avoidance of sucrose and all refined carbohydrates is extremely important.

Supplements

- Vitamin C: 3 to 5 g/day in divided doses
- Vitamin D: 2000 to 6000 IU/day
- Vitamin E: 400 to 800 IU/day
- Beta-carotene 50,000 IU/day
- Selenium: 400 mcg/day
- Zinc: 30 mg/day; used as a mouthwash with 15 mL of a 5% solution twice a day
- Folic acid: 800 mcg/day; used as a mouthwash with 15 mL of a 0.1% solution twice a day

Botanical Medicines

High-flavonoid–containing extracts such as those from bilberry *(Vaccinium myrtillus),* hawthorn (*Crataegus* species), grape seed *(Vitis vinifera),* or green tea *(Camellia sinensis)* can be used according to the dosages in the corresponding chapters. Of these extracts, grape seed extract or green tea extract (or the liberal consumption of green tea as a beverage) may offer the greatest protection. For a grape seed extract with a 95% proanthocyanidolic oligomer content or a green tea extract with a 90% polyphenol content, the dosage would be 150 to 300 mg a day. Additional recommendations follow:

- *Sanguinaria canadensis:* toothpaste containing extract
- *Centella asiatica* triterpenoids: 30 mg twice a day of pure triterpenoids

DIAGNOSTIC SUMMARY

- Unexplained abdominal pain, possibly including nausea and vomiting
- Acute peripheral or central nervous system dysfunction
- Mental abnormalities ranging from confusion to acute psychosis
- Urinary porphobilinogen during attack
- Most carriers are usually asymptomatic except when exposed to drugs or chemicals that exacerbate the condition

GENERAL CONSIDERATIONS

Until recently, porphyrias have been considered rare. It has only been within the past decade or so that an increasing number of patients have been diagnosed with these disorders, leading some clinicians to question their prevalence. Although allopathic medicine offers therapies that are effective in treating them, naturopathic medicine possesses a considerable array of therapeutic modalities that are effective in combating these diseases and preventing their recurrence.

Porphyria as a disease was first described three centuries ago by Sir Theodore Turquet de Mayerne of France, physician to the English court of King James I. He described accounts of paralysis, bilious urine, colic, insanity fits, permanent insanity, deaths at childbirth, and premature death in those afflicted. The disease probably afflicted King George III of England and was thought to have impaired his judgment during the American Revolution.[1]

In 1911, Günther described what is now known as the classic triad of abdominal pain, constipation (or diarrhea), and vomiting. Waldenström later added to the understanding of these diseases by describing acute intermittent porphyria (AIP) as characterized by periods of exacerbation and remission.[2]

Various classifications of porphyria were arrived at as greater recognition of their variations occurred. Genetic and environmentally induced manifestations of the disease were found, with considerable variations in the clinical presentations of the different forms.

The genetic deficits of porphyria affect all tissues but primarily the blood-forming tissues of the bone marrow and the cytochrome P-450 system in the liver because of the greater number of porphyrin precursors required. The liver is the major site where inherited or acquired deficits in heme synthesis occur.[3]

Classifications of Porphyria

Porphyrias are classified as being either hepatic or erythropoietic in origin. In both classes they are characterized by the overproduction of porphyrin or their precursors. Biosynthesis of heme is controlled differently in liver and bone marrow, with the rate-limiting enzyme in liver being aminolevulinic acid (ALA) synthase, whereas the biosynthesis of heme in the bone marrow is partly regulated by the uptake of iron.

Acute hepatic porphyrias are characterized by a rapid onset of symptoms that are largely neurologic; the erythropoietic variety manifests primarily in the skin, leading to cutaneous photosensitivity (Box 200-1).

Signs and Symptoms of Hepatic Porphyrias

Acute attacks are comprised of a wide variety of symptoms, ranging from skin lesions to abdominal pain to neurologic manifestations of varying intensity. Abdominal,

BOX 200-1 **Primary Porphyrias**

Hepatic Porphyrias	Erythropoietic Porphyrias
ALA-dehydrase-deficiency porphyria	X-linked sideroblastic anemia
Acute intermittent porphyria	Congenital erythropoietic porphyria
Porphyria cutanea tarda	Erythrocytic protoporphyria
Hereditary coproporphyria	
Variegate porphyria	

Modified from Braunwald E, ed. Harrison's principles of internal medicine, ed 15. New York: McGraw-Hill, 2001.
ALA, Aminolevulinic acid.

back, or extremity pain grows in intensity over a 24- to 48-hour period, which may lead the clinician to consider appendicitis or an acute abdomen. Rebound tenderness is not usually present.

Nausea and vomiting are frequently seen, as are anxiety and restlessness. Often these patients have some degree of constipation that worsens as the condition develops. Tachycardia may also be present, suggesting an infectious process or increased bowel toxicity.

In general the severity of the symptom pattern seems to the clinician to be out of proportion to the manifesting signs. It is thought that the bowel symptoms are due to a neurologic disturbance of normal function.

Mental abnormalities can range from confusion to acute psychosis and may be the first presentations of an attack. With prolonged attacks, sensory and motor functions are impaired and can result in respiratory paralysis and death.[5] Many patients are diagnosed with schizophrenia, and a considerable number confined to mental institutions are thought to be afflicted with one of the porphyrias.[6,7]

The majority of carriers are usually asymptomatic except when they are exposed to drugs or chemicals that exacerbate the condition. Neurologic symptoms and the sequelae of an acute or prolonged attack can take months to clear, but eventual recovery occurs in the majority of cases.

BIOCHEMISTRY OF PORPHYRIA

The biosynthesis of heme is the main purpose of the porphyrogenic pathway. Heme, a high-molecular-weight metalloprotein, is a member of a group of chemicals that include cytochromes (oxidation/reduction reactions), chlorophyll (photosynthesis), and vitamin B_{12}. Heme is formed from succinyl coenzyme A (CoA) and glycine; after being combined with globin chains, it is ultimately involved in aerobic metabolism. These globin chains are synthesized on the ribosomes in the plasma of the developing erythrocyte. In the liver, heme production is largely used for the production of cytochrome P-450 in response to the body's need to eliminate toxic substances. Heme synthesis begins and ends in the mitochondrion, with part of it occurring in the cytoplasm. All tissues form heme, but the primary sites are the bone marrow and liver.

The rate-limiting enzyme for heme synthesis is ALA synthase, which is the initial enzyme in the cascade. ALA synthase requires vitamin cofactors and energy input. All other reactions in the sequence are the result of thermodynamics and are irreversible once initiated.

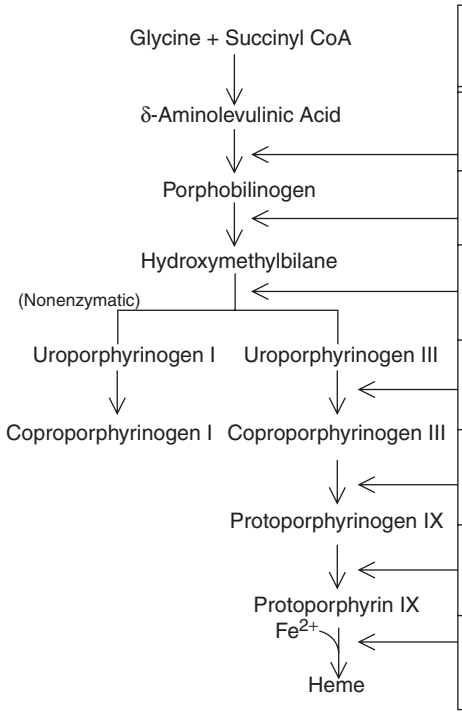
ALA synthase is regulated by a feedback mechanism that is responsive to the tissues' demand for heme production. With the formation of uroporphyrinogen, branching occurs and results in different porphyrin isomers. Isomer I proceeds only as far as coproporphyrin I and normally is considered inconsequential. Isomer III results in the formation of uroporphyrinogen III, which undergoes modification to render it more lipophilic so that it can be excreted from the body. Thus, most of the pathway favors heme production.

Heme Formation

Final heme formation is regulated by the action of ferrochelatase in the mitochondria. Reducing substances such as ascorbic acid, cysteine, or glutathione are required. Iron must be in the ferrous rather than ferric form. Ferrochelatase activity is inhibited by high concentrations of heme. Thus, the feedback system prevents further formation. Heme concentration also feeds back on ALA synthase, the rate-limiting step in the biosynthetic pathway.

Because heme formation is essential for aerobic metabolism, its absence would be lethal. Therefore, multiple control systems have evolved to regulate the metabolic pathway, which has made it difficult to elucidate the exact mechanism of the deficit, be it genetic or acquired. Recent advances in identifying specific DNA encoding the heme biosynthetic enzymes, however, has resulted in a more precise diagnosis of the specific genetic deficit.

Red blood cell (RBC) incorporation of heme, iron, and glycine occurs in maturing cells up through and including reticulocytes but is eventually lost as the red cell ages. Hypoxia and erythropoietin will increase ALA synthase activity in RBCs but not the liver, whereas drugs and chemicals will affect the liver but not erythropoietic tissues. Figure 200-1 illustrates heme synthesis and porphyria.



MANIFESTATION OF PORPHYRIA

In patients with porphyria, specific genetic or acquired deficiencies limit the flow of heme precursors through the cascade of steps needed to form hemoglobin. The deficiency can become manifest owing to an increased demand for heme precursors. Certain drugs, chemicals, steroids, estrogens, oral contraceptives, progesterone, testosterone, or any substance that places an excess burden on the cytochrome P-450 system can act to precipitate an acute attack. This results from the partial removal of the feedback mechanism on delta-ALA synthase. Depending on the specific enzyme deficit present, heme precursors follow different pathways resulting in their accumulation in the tissues. Their presence affects the skin and nervous system and manifests as the signs and symptoms of the disease.

Attacks occur more frequently in women than men, especially premenstrually. As the person ages, the likelihood of exposure of an underlying porphyria deficit increases because of increased exposures to environmental toxins and the aging body's decreasing ability to adapt.

Cutaneous manifestations occur because some porphyritic precursors absorb light at 400 nm, resulting in photosensitivity. The absorption of light raises the potential energy of the molecule to an "excited" state, resulting in a highly reactive oxygen species. The release of histamine and proteolytic enzymes then results in oxidative damage. Beta-carotene protects against these injuries.[3,4,8]

Neuropsychiatric changes occur in the hepatic porphyrias (ALA-dehydrase-deficiency porphyria, AIP, porphyria cutanea tarda, hereditary coproporphyria, and variegate porphyria) with excess production of ALA and porphobilinogen (PBG), and there is a somewhat linear relationship between their concentration and the severity and duration of symptoms. A buildup of porphyrin intermediaries has been found in various tissues and may induce the neuropsychiatric symptoms accompanying acute flareups.[9,10] The exact mechanism whereby porphyrins affect the central nervous system is not well understood.

Enzyme	Disease	Major Symptoms	Accumulation Products
δ-Aminolevulinate Dehydratase	ALA-Dehydrase-Deficiency Porphyria	Neurovisceral	Urinary ALA
Porphobilinigen Deaminase	Acute Intermittent Porphyria	Neurovisceral	Urinary ALA and PBG
Uroporphyrinogen III Cosynthase	Congenital Erythropoietic Porphyria	Photosensitivity	Erythrocyte and Urinary Uroporphyrin I and Coproporphyrin I
Uroporphyrinogen Decarboxylase	Porphyria Cutanea Tarda; Hepatoerythropoietic Porphyria	Photosensitivity	Urinary 7-Carboxylate Porphyrin; Fecal Isocoproporphyrin
Coproporphyrinogen Oxidase	Hereditary Coproporphyria	Neurovisceral and Photosensitivity	Urinary ALA, PBG, and Coproporphyrin; Fecal Coproporphyrin
Protoporphyrinogen Oxidase	Variegate Porphyria	Neurovisceral and Photosensitivity	Urinary ALA and PBG; Fecal Protoporphyrin
Ferrochelatase	Erythropoietic Protoporphyria	Photosensitivity	Erythrocyte, Plasma, and Fecal Protoporphyrin

FIGURE 200-1 The heme synthesis and porphyria. (From Sassa S, Kappas A. The porphyrias. Scientific American medicine. New York: Scientific American, 2003:9:V:1-9.)

Patients with familial porphyria cutanea tarda (PCT) usually present at a younger age than those who develop PCT spontaneously, despite the fact that there is no difference in the biochemical features of the disease.[11] This may be because of a corresponding genetic predisposition to sequester ferritin in the liver or an increased sensitivity to ethanol ingestion.[11,12] Additionally, even in families with known genetic deficits, manifestations of the disease among family members vary.

Etiologic Agents Triggering Porphyria

Numerous agents that trigger episodes of porphyria have been identified, and patients afflicted must be careful when taking prescription medications, estrogens, and some herbal medicines; they must also avoid environmental exposures to heavy metals, organophosphates, and any substance that places an excess burden on the cytochrome P-450 system. In particular, exogenous estrogens—whether from oral contraceptives, estrogen patches, or estrogen replacement therapy—are strong contributors to an underlying porphyria deficit.[13,14] This is one reason why acute attacks of porphyria are seen more often in women than men, especially premenstrually. Additionally, some studies have suggested that estrogens enhance the porphyrin-inducing activities of other agents, making women more vulnerable to environmental exposures than their male counterparts.[15,16]

Herbicide-induced porphyria has been shown to decrease the activity of several enzymes involved in the porphyritic pathway as well as to increase the porphyrin content in nerve tissue.[16,17] A considerable number of chemicals have also been linked to porphyria or porphyrinuria in humans; these generally involve chronic industrial exposures or environmental exposures. An example of an epidemic of PCT produced by the accidental ingestion of wheat treated with the fungicide hexachlorobenzene occurred in Turkey in the 1950s.

Some researchers have hypothesized that several otherwise unexplained chemical-associated illnesses such as multiple chemical sensitivity syndrome (MCSS) may represent mild chronic cases of porphyria or other acquired abnormalities in heme synthesis.[18,19]

According to William Morton, who has written extensively on porphyrias, MCSS as first described by Cullen in 1979 may, in fact, be porphyria. Morton speculates that exposures to porphyrogenic chemicals, medications, or severe infection overpower the already deficient enzyme system, resulting in an accumulation of the specific porphyrin because of diminished enzyme function. He proposed that the resultant symptoms are due to an increase of the porphyrinogen and not an accumulation of the toxin itself. Many diagnosticians have tried to expedite the distinction between "real" porphyria and secondary porphyrinopathies by requiring that a porphyria diagnosis be based on urinary or fecal porphyrin excretions or both 2 to 20 times the upper limit of normal. This classification would exclude individuals demonstrating lesser degrees of porphyrinogenic activity, possibly some of those whose conditions are in remission or not subject to environmental exposures.[20]

The intensity of porphyria symptoms varies widely. About 10% of the cases present with acute severe attacks, whereas approximately 25% are seen with chronic symptomatology of varying degrees. The remaining percentage (65%) present with no symptoms but may become susceptible under the right circumstances.[21]

Not all researchers agree with Morton's and others' premise that environmental toxicities induce underlying genetic deficits leading to symptomatic porphyria. According to Hahn and Bonkovsky, "patients with multiple chemical sensitivity syndrome may, at times, have modest increases in urinary coproporphyrin excretion; this is a common finding found in many asymptomatic subjects or patients with diverse other conditions (e.g., diabetes mellitus, heavy alcohol use, liver disease, and many kinds of anemia). Such secondary coproporphyrinuria does not indicate the existence of coproporphyria."[22]

Regardless of which view is correct, an increasing number of cases are being diagnosed by clinicians. Certainly, with the increasing levels of pollutants in the environment, hormonal additives to

the food chain, and the unmonitored multiple pharmacy prescriptions encountered by most humans, the potential for unmasking an underlying deficit increases.

LABORATORY DIAGNOSIS OF PORPHYRIA

Small amounts of porphyrins are excreted in normal human urine, the most predominant of which is coproporphyrin. Coproporphyrin is also present in the bile and feces. ALA, PBG, and uroporphyrin are largely excreted in the urine, whereas coproporphyrin is preferentially and protoporphyrin exclusively excreted in the bile and feces.

Fecal excretion is also affected by diet and bowel flora, thus contributing to its wide variation. Geographic distribution, dietary preferences, ethnic diversities, and differences in test methodologies make it difficult to arrive at "normal" values.

PBG excretion in the urine of healthy individuals is usually below 1.5 mg/day and is undetectable by conventional testing. The Watson-Schwartz qualitative test for PBG will be positive in acute attacks of AIP and variegate porphyria and hereditary coproporphyria in latent periods.[23] There is a high false-negative rate owing to its subjective nature. A false increase in porphyrins from a substance present in yeast tablets has been demonstrated to produce a false-positive Watson-Schwartz test.[24]

A cost-effective strategy for the diagnosis of porphyric syndromes in the presence of acute symptoms has been suggested:

> *If neurovisceral features suggest an acute porphyric syndrome, a rapid screening test for urinary porphobilinogen should be performed. If clinical features suggest a cutaneous porphyria, then for solar urticaria and acute photosensitivity (suggesting protoporphyria) screening tests for increased erythrocytic porphyrins should be done; for vesiculobullous formation (suggesting porphyria cutanea tarda, hereditary coproporphyria, or variegate porphyria) a screening test for urinary porphyrins should be done. Positive screening tests should be confirmed with targeted quantitative testing.*[25]

Enzymatic assays and DNA-based testing are not usually necessary for the rapid diagnosis or management of symptomatic subjects with acute disease. Such tests are, however, useful for evaluation and genetic counseling. Isolation of specific DNA encoding the heme biosynthetic pathway enzymes makes it possible to now provide precise heterozygote identification as well as prenatal diagnosis in families with known defects.[4,25,26]

Other cell markers may also help in identifying porphyria patients in the absence of symptoms. Leukocyte concentrations of manganese, calcium, iron, zinc, and erythrocyte calcium have been shown to be present at different concentrations between groups classified as AIP gene carriers. Of the cell markers, manganese was found to be the most discriminative component of all the variables investigated. An increase in cellular manganese by a factor of four suggests an increase in the likelihood of development of AIP.[27]

Because of the many possible genetic deficits leading to porphyria, it is important that the specific deficit be determined, because successful treatment outcomes depend on the correct diagnosis.

See also Chapter 29 for more discussion of the diagnosis of porphyrinopathies.

THERAPEUTIC CONSIDERATIONS

It is important to identify patients who are predisposed and susceptible to the development of porphyritic episodes. On seeing a patient with a past medical history of periodic psychotic episodes or nervous breakdown, unexplained abdominal pain, or unusual symptoms that have led to numerous diagnoses, the physician should be alerted to the possibility of an underlying porphyria. Prevention is clearly the first option, because porphyritic episodes can be difficult to control once initiated.[28]

The treatment of patients afflicted with acute episodes of porphyria can be demanding and owing to the severity of the condition and the unstable clinical picture. Each patient presentation is different depending on the degree of toxicity, genetic component, and patient response to therapy.

Homeopathic treatment has proved successful, but different homeopathic medicines are required depending on the clinical picture, which, as has been mentioned, can change quickly. Constitutional prescribing does not seem to work as well when the patient is in an acute state, and several prescriptions may be necessary to help the patient to become stable. The prescriptions may have to be changed frequently as the patient progresses through the varying stages of the disease.

During an acute episode, frequent follow-up is necessary in order to assess the clinical state. In some cases, patients must be seen daily and medications altered depending on the presentation.

Education of the patient as to his or her condition is one of the most important tasks. Often the patient does not want to believe that a genetic affliction exists and will seek another diagnosis. He or she has often received various diagnoses and may still believe that this condition is another disorder. It will be important to delineate which symptoms go with each condition, but they will all probably be related to the porphyria. Additionally, informing other physicians seen by the patient as to his or her condition will help to keep prescription drugs to a minimum, thus decreasing the likelihood of an exacerbation.

The course of therapy required for the patient to reach a state where he or she is not as susceptible to environmental toxins is usually long and involves periods of exacerbation and remission. Helping the patient to understand this will facilitate the recovery.

Environmental and chemical exposures must be eliminated by identifying offending agents and limiting exposures. Lists of prescription medicines and environmental toxins that cause exacerbation of porphyria are available (Boxes 200-2 and 200-3). A complete history as to environmental and work-related exposures is in order. Often, simply by changing the patient's work environment, exposures will be decreased and attacks eliminated.

BOX 200-2 Toxins Known to Cause or Exacerbate Porphyria

Intoxications
- Alcoholism
- Foreign and environmental chemicals (e.g., hexachlorobenzene, polyhalogenated biphenyls, dioxins [2,3,7,8-tetrachlorodibenzo-p-dioxin], vinyl chloride, carbon tetrachloride, benzene, chloroform)
- Heavy metals such as lead, arsenic, and mercury
- Drugs

Adverse Effect of Drugs
- Analgesics
- Sedatives
- Hypnotics
- Anesthetics
- Sex hormones
- Sulfa-drug antibiotics

P
Q
R

Diet

During attacks of AIP, an increased intake of complex carbohydrates can help to alleviate symptoms. Often the patient is ingesting high amounts of carbohydrates when first seen, and weight gain often follows. Intravenous glucose can also be given (300 to 400 g/day). A more complete parenteral nutritional regimen is preferable, however. Fasting or rapid-weight-loss diets can precipitate AIP and should be avoided.

A diet rich in high-fiber fruits and vegetables has been shown to be remarkably effective in improving several measures of porphyria. A 3-week study of 13 male PCT patients found that 500 kcal/day of fruits and vegetables resulted in a significant decrease in body-mass index from 26.8 to 25.8, serum ALT activity from 122 to 75.6 U/L, serum AST from 91.8 to 55.2 U/L, serum iron levels from 188.6 to 140.2 mg/dL, and serum ferritin concentrations from 574 to 499 ng/mL. Skin lesions also improved, and urinary coproporphyrin excretion decreased. There was a statistically insignificant reduction in uroporphyrin excretion.[30]

BOX 200-3 Drugs Known to Cause or Exacerbate Porphyria*

- Antipyrine
- Aminopyrine
- Aminoglutethimide
- Barbiturates
- Captopril
- Carbamazepine
- Carbromal
- Chloral hydrate
- Chloramphenicol
- Chlordiazepoxide
- Chlorpropamide
- Danazol
- Dapsone
- Diazepam
- Diclofenac
- Diltiazem
- Diphenhydramine
- Diphenylhydantoin
- Doxycycline
- Ergot preparations
- Erythromycin
- Estrogen
- Ethanol (acute)
- Ethchlorvynol
- Ethinamate
- Furosemide
- Glutethimide
- Griseofulvin
- Hydralazine
- Hydrochlorothiazide
- Imipramine
- Isopropyl meprobamate
- Lidocaine
- Mephenytoin
- Meprobamate
- Methyldopa
- Methylprylon
- Metoclopramide
- Metronidazole
- N-butylscopolammonium bromide
- Nifedipine
- Nitrous oxide
- Novobiocin
- Oral contraceptives
- Orphenadrine
- Oxycodone
- Pentazocine
- Phenobarbital
- Phenylbutazone
- Phenytoin
- Piroxicam
- Pivampicillin
- Primidone
- Progesterone
- Pyrazimide
- Pyrazolone preparations
- Sodium valproate
- Succinimides
- Sulfonamide antibiotics
- Sulfonethylmethane
- Sulfonmethane
- Synthetic estrogens, progestins
- Terfenadine
- Tetracyclines
- Theophylline
- Tolazamide
- Tolbutamide
- Trimethadione
- Valproic acid
- Verapamil

Modified from Sassa S, Kappas A. The porphyrias. Scientific American medicine. New York: Scientific American, 2003:9:V:1-9.
*Although this list includes many of the better-known drugs that can exacerbate porphyria, it should not be considered complete.

Antioxidants

Antioxidant therapy, along with homeopathy, is the mainstay of case management during acute porphyritic episodes.[31] Once the patient has stabilized, an ongoing regimen of antioxidants such as vitamin C, vitamin E, glutathione, beta-carotene, and *N*-acetylcysteine should be undertaken in order to prevent recurrence.[32] Vitamin C has been found to be low in PCT patients.[33] Subjective evaluation of the use of high-dose vitamin C (1 g a day) compared with placebo was conducted in 12 patients with erythropoietic protoporphria photosensitivity for a period of 4 weeks. Although there was no statistical significance to the fact that patients fared better on the high-dose vitamin C, 8 of the 12 participants reported less sensitivity to sunlight.[34]

High-dose vitamin E supplementation (1 g/day of alpha-tocopherol) in patients with PCT decreased urinary excretion of uroporphyrins (50% of the C8 carboxyls), with clinical improvement in all patients.[35] The effect lasted only as long as vitamin E was being supplemented. Treatment with vitamin E was found to reduce residual oxidative stress while not affecting increased plasma and whole-blood viscosity present in PCT patients who were receiving only phlebotomy treatment prior to clinical remission.[36]

Combinations of antioxidants are also being looked at as a mode of treatment for the various porphyrias. A study comparing the protective ability of several antioxidants used concurrently for the phototoxicity of protoporphyrin IX (PP IX) and uroporphyrin I (UP I) was conducted on cell cultures. The researchers found that cell growth and cell membrane protection showed differences in protection for the two types of porphyrias. Both beta-carotene and lycopene and the combination of beta-carotene, ascorbic acid, and alpha-tocopherol offered cell protection against PP IX phototoxicity. For membrane protection, there was significant protection against UP I by the combination of beta-carotene, ascorbic acid, and alpha-tocopherol as compared with any of these antioxidants alone. The authors concluded that a combination of beta-carotene, ascorbic acid, and alpha-tocopherol offers membrane protection against the phototoxicity of both porphyrins, which is believed to occur as a result of synergistic processes. Their results suggest that the treatment of porphyria cutanea tarda and erythropoietic protoporphyria may be improved by the use of a combination of the antioxidants studied.[37]

Additionally, it is thought that the increase in oxidative damage from photodermatitis would contribute to lower vitamin D levels. Lower levels of vitamin D have been implicated more recently as contributing to a number of medical conditions such as stroke, osteoporosis, hip fracture, and muscle weakness.[38] A cohort of 201 patients with known erythrocytic protoporphyria (EPP) was evaluated over a 7-month period for the deficiency of vitamin D levels due to lowered sun exposure. Thirty-four patients (17%) were deficient in vitamin D and 126 (63%) were found to have insufficient levels of vitamin D. Both insufficiency and deficiency were significantly associated with the total erythrocyte protoporphyrin concentration and inversely with the time in minutes to the onset of symptoms following sunlight exposure. The authors concluded that in patients with porphyrias associated with photodermatitis, vitamin D therapy should be considered.[39]

In two studies, melatonin as an antioxidant was evaluated for its effects on delta-aminolevulinic acid–induced oxidative toxicity in neural tissue and as a cotreatment in patients suffering from disturbances related to ALA accumulation. In in vivo experiments it was demonstrated that lipid peroxidation induced by delta-aminolevulinic acid (40 mg/kg) in the cerebellum and hippocampus was reduced by

acute melatonin (10 mg/kg) administration.[40] In the other study it was concluded that melatonin had marked efficacy in protecting against ALA-related oxidative stress and its oncostatic properties. Moreover, it was concluded that its low toxicity constituted a reason to consider the use of melatonin as a cotreatment in patients suffering from disturbances related to ALA accumulation.[41]

B-Complex Vitamins

Because pantothenic acid is required for the formation of succinyl CoA (generated by the tricarboxylic acid cycle) and glycine, which are the precursors to formation of ALA, supplementation is helpful. Additionally, a step in the transformation of succinyl CoA requires a vitamin B_{12}–dependent enzyme, and evaluation of vitamin B_{12} and folic acid status may be in order. The initial reaction is oxygen-dependent, which may mean that oxygen therapy is contraindicated in delta-ALA porphyria.

ALA formation requires and is dependent on pyridoxal-5-phosphate; hence, any substance that inhibits enzyme systems is countered in part by the addition of pyridoxal-5-phosphate. However, experimental models suggest that this agent does not play an important role.[3]

Carotenoids

All cutaneous porphyrias can be alleviated by the avoidance of sunlight. Treatment of erythropoietic protoporphyria with large doses of beta-carotene has been effective and may improve tolerance to sunlight.[42] Another study showed that mixed carotenoids (alpha-carotene, beta-carotene, and lycopene) were effective in cell cultures, although any one of these used alone was ineffective.

Iron

Several lines of evidence suggest that excessive iron stores and consumption aggravate some porphyrias.[43] Iron should be avoided unless supplementation is clearly indicated by low iron stores.

Detoxification

Detoxification of the liver and colon is indicated as an ongoing process to eliminate toxins that may exacerbate the condition. Regardless of whether the toxin actually precipitates an attack of porphyria, elimination on an ongoing basis reduces the chance of an acute flareup of the disease. Detoxification can be achieved through colon hydrotherapies, constitutional hydrotherapies, saunas, antioxidants, or oxygen therapies such as ozone.

Supplementation with lipotrophic factors that enhance the function of the liver's cytochrome P-450 system are contraindicated during acute attacks but useful when the patient is in a period of normality. Incorporating them, as well as high doses of antioxidants, helps decrease the number of acute attacks.

Additionally, chelation therapies with ethylenediamine tetraacetic acid and ethanol extracts of botanical medicines are contraindicated in patients with a predisposition to developing porphyria.

Constitutional Hydrotherapy

Constitutional hydrotherapy during an acute flareup is effective in normalizing liver function as well as neurologic symptoms. Daily sessions may be necessary to accomplish this, while allowing the physician to monitor the patient closely.[44]

Ozone Therapy

Ozone therapy is primarily indicated when there is a deficit of coproporphyrinogen oxidase, resulting in a deficit of coporphyrinogen in hereditary coproporphyria. It is contraindicated when there is a deficit of ALA synthase, because higher amounts of oxygen enhance the pathway and exacerbate the symptoms.

THERAPEUTIC APPROACH

The primarily clinical approach is to identify the condition early and avoid irritating and aggravating factors. Sun exposure should be limited when cutaneous manifestations are present.

Diet

The patient's diet should be rich in fruits and vegetables and low in iron.

Supplements

- Vitamin E: 400 to 1200 IU/day
- Mixed-carotenes: 100,000 to 150,000 IU/day
- Vitamin C: 3000 to 5000 mg/day
- Vitamin D: 5000 to 10,000 IU/day (measure blood levels to determine optimal dosage)
- Melatonin: 3 mg/day

CHAPTER 201

Pregnancy Health and Primary Prevention of Adult Disease

Pina LoGiudice, ND, LAc, and Peter B. Bongiorno, ND, LAc

INTRODUCTION

Pregnancy provides a unique opportunity for the practitioner to help create a healthful environment for the benefit of the mother and to positively affect the future offsprings health. The health care provider can use this time to educate and empower parents to create optimal conditions for the future health of the family.

There is a growing body of evidence suggesting that increased susceptibility to chronic disease in adulthood originates in part during fetal development.[1] In utero gene expression is highly sensitive to environmental changes, which can lead to altered function, metabolism, and hormone production.[2] In utero environmental exposures alter phenotypic expression via DNA methylation, histone acetylation, messenger RNA expression, and chromatin structure modification. These epigenetic changes occurring in the womb are replicated throughout life, and may even be passed to subsequent generations.

Preconceptive Work

It should be noted that if the practitioner has the opportunity to work with the pregnant mother before pregnancy, natural considerations to detoxify, replete deficient nutrients, and lower stress would be ideal before conception in order to optimize the in utero environment.

Pregnancy Death Rates and Premature Births

According to the World Health Organization (WHO), the pregnancy death rate has decreased by 30% in the last 20 years. This decline is due to both a worldwide increase in the training of midwives as well as higher quality pregnancy care in higher-risk community health centers and hospitals. Pregnancy deaths are about 36 times greater in a developing country versus a developed country. The main causes of such deaths are severe bleeds after childbirth, infections, hypertension, and improper abortion.[3] With more than 540,000 yearly premature births, the United States has a significantly higher rate of infant mortality compared with other developed countries owing to the inadequate pregnancy care received by poor women, increased infertility treatments (which raise the odds of multiple births), and early labor and delivery.[4]

Weight Gain

On average, women should expect to gain from 25 to 35 pounds during a normal pregnancy, with a typical 3- to 4-pound gain during the first trimester (Table 201-1). Low weight gain is associated with increased intrauterine growth restriction risk and perinatal mortality. The overall weight gain represents two components: (1) the products of conception (fetus, amniotic fluid, and placenta) and (2) maternal accretion of tissues (expansion of blood and extracellular fluid, enlarged uterus and mammaries, and adipose stores).

Obesity in Pregnancy

Animal studies reveal that high maternal weight or weight gain during pregnancy leads to changes in the hypothalamus, pancreatic islet cells, fat tissue, endocrine physiology, and metabolic pathways affecting homeostatic weight control.[5] Excessive gains are

TABLE 201-1 **Current Recommendations for Weight Gain During Pregnancy**

Prepregnancy BMI	BMI (kg/m^2) (WHO)	Total Weight Gain Range (lb)	Rates of Weight Gain 2nd and 3rd Trimesters (lb/wk)
Underweight	<18.5	28–40	1 (1–1.3)
Normal weight	18.5–24.9	25–35	1 (0.8–1)
Overweight	25.0–29.9	15–25	0.6 (0.5–0.7)
Obese (includes all classes)	≥30.0	11–20	0.5 (0.4–0.6)

Data from the Institute of Medicine. Weight Gain During Pregnancy: Reexamining the Guidelines.Washington DC: National Academy Press; 2009.

associated with gestational hypertension, labor augmentation, high birth weight, cesarean sections, neonatal metabolic abnormalities, and fetopelvic disproportion complicates the risk.[6]

According to the Centers for Disease Control (CDC), 20% of women are obese at the onset of pregnancy. Babies born to obese women are nearly three times more likely to die within the first month of birth, and stillbirth rates are doubled. Very obese women, or those with a body-mass index of 35 or higher, are three to four times as likely to deliver their first baby by cesarean section versus first-time normal-weight women.[7] Weight gains of 6.7 to 11.2 kg (15–25 lb) in overweight and obese women, and less than 6.7 kg (15 lb) will reduce risk. Interestingly, in morbidly obese women, poor weight gain was associated with 30% less use of epidural analgesia and an overall reduction in negative outcomes.[8]

Thyroid

With normal thyroid function needed for pregnancy success, the need for thyroxine increases in many women.[9] Preterm delivery, preeclampsia, hypertension, diabetic complications, placental abruption, miscarriage, and adverse fetal effects have all been reported with hypo- or hyperthyroidism during pregnancy.[10]

Normal thyroid stimulating hormone (TSH) levels alone do not assure proper thyroid function. Normal TSH accompanying autoimmunity creates a twofold risk for pregnancy loss.[11] Although TSH laboratory values range between 0.45 and 4.5 mIU/L, studies suggest that that the upper range cutoff in the pregnancy TSH should be around 2.5 mIU/L.[12] Miscarriage and preterm delivery increase with higher levels. Furthermore, women with positive antibodies and no replacement therapy also have higher rates of miscarriage than women with positive antibodies and levothyroxine replacement (13.8% vs. 3.5%).[13]

Women planning to undergo fertility treatment may benefit from thyroid antibody screening and thyroid replacement if antibodies are found, especially if clinical symptoms are present. Symptoms can include fatigue, dry skin, constipation, slowed mentation, and low body temperature. Women with otherwise unexplained previous pregnancy losses probably should be treated if their TSH level is above 2.5 mIU/L and/or they have a positive test for antibodies.

One study of 4,123 thyroid antibody–free women found a 3.6% rate of pregnancy loss in women with a TSH level greater than 2.5 mIU/L and double that rate (6.1%) in women with TSH levels between 2.5 and 5.0 mIU/L. Age, obstetric history, and even thyroid function tests did not differ between those who miscarried and those who did not. Statistically, the risk of miscarriage increased by 15% for each elevation of 1 mIU/L in the TSH level. Preterm and very preterm delivery risks did not differ with TSH levels.[14]

BOX 201-1 **Adjuvant Ingredients**

- Squalene
- Polysorbate 80
- Sorbitan triolate
- Sorbitan oleate
- Polyethylene cetostearyl ether
- Mannitol
- Aluminum hydroxide
- Aluminum phosphate
- Aluminum hydroxyphosphate sulfate

Preeclamptic women are more likely to have hypothyroidism before conception or in late pregnancy. After the onset of preeclampsia, predelivery TSH increased 2.42 times above baseline versus 1.48 times in controls. Toward the end of pregnancy, women with preeclampsia had, in general, much higher levels of TSH than women with no history of preeclampsia.[15]

Flu Shots and Vaccines

In pregnancy care, it is generally recognized as reasonable to avoid any unnecessary treatment. Vaccination during pregnancy is a controversial topic in both conventional and natural medicine.

Vaccination is recommended in several countries, and no studies demonstrate an increased risk of maternal or fetal adverse effects with inactivated, unadjuvanted shots.[16,17] The U.S. Advisory Committee on Immunization Practices recommends the influenza vaccine in pregnancy, citing increased risks of flu complications in pregnant women. There is a 41% decreased incidence of flu in infants born to vaccinated women as well as a 39% decrease in influenza-like illness and hospitalization. Infant antibody titers were significantly higher with vaccinated pregnant mothers. It should be noted that one of the study authors received grants from three companies that manufacture influenza vaccine.[18]

Newer vaccines, such as the influenza/H1N1 vaccine, now include adjuvant, which may induce a stronger immune response in pregnant individuals, because they have been shown to be more sensitive to proinflammatory stimuli than those who are not pregnant.[20] An adjuvant (Box 201-1) is a substance that, when administered in combination with a specific antigen, enhances the immune response against the antigen when compared with use of the antigen alone. Many pregnant women were vaccinated with the adjuvanted H1N1 pandemic influenza vaccine at a time when its safety had not been tested.[20]

The CDC Advisory Committee on Immunization Practices in pregnancy[21] supports giving pregnant women a number of vaccinations during pregnancy and lists only two as contraindicated. These are listed in Box 201-2.

LIFESTYLE FACTORS

Hydration

Vital for a healthful pregnancy, appropriate fluid intake hydrates all body cells and provides a normal 40% volume expansion in the pregnant woman.[22] About 32 ounces of fluid surround the baby as amniotic fluid, which is replaced every third hour. Insufficient fluid intake can cause constipation, preterm labor, temperature dysregulation, cystitis, miscarriage, and fatigue. Proper hydration is also important for subsequent breast milk production and flow.

BOX 201-2 Vaccination Recommendations from the CDC Advisory Committee on Immunization Practices in Pregnancy

Tetanus, diphtheria, pertussis	**Contraindicated Vaccines:**
Hepatitis A	Measles, mumps, rubella
Hepatitis B	Varicella
Influenza	
Pneumococcus	
Polio	
Typhoid-nonlive	

Data from Zain A, Al-Safi Valerie I, Shavell VI, Gonik B. Vaccination in pregnancy. *Women's Health* 2011;7(1):109-119.

With 96 ounces of fluid loss via urination and perspiration per day, each pregnant women needs between 8 and 12 eight-ounce glasses of water or other beverages per day. Weather that is warmer than usual and dry, cold weather both increase moisture loss. The pregnant woman should avoid heavily caffeinated drinks and sugary beverages. It is best to drink at regular intervals and not wait for the feeling of thirst.

Energy Needs and Diet

Pregnancy is a demanding anabolic state that hormonally redirects nutrients to maternal reproductive tissues and the developing infant.[23] Pregnancy leads to a modest increase of energy needs on the order of 375, 1200, and 1950 kJ daily for the first, second, and third trimesters of pregnancy respectively,[24,25] which can normally be met by modest increases in consumption of a balanced diet. The 2002 Dietary Reference Intake Report set a minimum level of 175 g carbohydrate per day for pregnancy, which includes an additional 33 g carbohydrate for fetal brain development and functioning over nonpregnant women. There is no indication that recommendations for dietary total fat intake, expressed as a percentage of energy intake, need to differ from those for nonpregnant women.[26] With micronutrient deficiencies common during pregnancy (even in well-fed populations),[27] it is important to consider a prenatal multivitamin along with a healthful diet.

Under- and Overnutrition

Undernutrition during pregnancy and low birth weight epigenetically increase the risks of diabetes and cardiovascular disease in adulthood.[28] In birth cohorts conceived during the height of the Dutch Hunger Winter famine of 1944–1945[29] and the severe China famine, from 1958–1961,[29,30] fetal effects included higher weight and waist circumferences, higher adult BMIs, increased risk of hypertension, impaired glucose tolerance,[31] increased risk for cardiovascular disease[32] and diabetes,[33] and a twofold increase in the incidence of schizophrenia[34] and both mood and schizoid personality disorders.[35]

Excess and unbalanced food choices will also have a negative impact on the health of the offspring via high birth weight, which increases the risks for obesity and diseases such as cancer and asthma later in life. It is appropriate for a baby to be born with some adipose tissue, but excess fat is indicative of abnormal fetal development.[5]

Healthful dietary changes after a baby is born may not be able to reverse the original fetal insult. Pregnant rats fed an unhealthy diet are more likely to have offspring that develop breast cancer, likely due to the in utero effect on mammary remodeling. Even when daughters eat healthily, their disease risk is still not ameliorated. Interestingly, daughter rats with grandmothers who ate a fatty diet were even more at risk. In one study at 20 weeks, 50% of the rats whose grandmothers ate a normal diet developed breast tumors, whereas 80% of rats with two grandmothers fed a high-fat diet grew tumors and 68% of the rats with just one such grandmother developed cancer. These animal studies strongly suggest that a fatty diet may cause epigenetic DNA modifications that can be passed on to future generations.[36]

The brain and nervous system are also subject to the epigenetic changes of a high-fat diet. One study looked at three different pregnancy diets: the first diet was high in saturated fat, the second was high in unsaturated or "trans" fat, and the third was a control low-fat diet. At weaning and in adulthood, proinflammatory cytokine expression was strikingly increased in the periphery and hippocampus following a bacterial challenge in the high-fat and trans-fat groups compared with controls. Anxiety was significantly increased in fat-exposed offspring, particularly males, and there was a negative effect on learning. These effects were all observed in adulthood, even after the pups were placed on standard chow at weaning, suggesting that these outcomes were programmed in utero. The findings suggest that maternal diet will program brain changes that begin before birth and that these cannot be reversed in the offspring with a change in diet.[37]

Healthy Foods

Fruits and Vegetables

Pregnant women require more fruits and vegetables than usual because of the extra demands on the body. One study of 1034 women reported dose-dependent reductions in urinary tract infection with an increased intake of *both* fruits and vegetables, not either alone.[38] The recommendation is seven servings per day of fruits and vegetables during pregnancy. A serving size for fruit or vegetables is one half cup. Less dense greens like spinach and lettuce have a serving size equal to one full cup.[39]

Folic Acid–Containing Foods

Given the well-known association between deficiency of folic acid during the prenatal period with spina bifida and other neural tube defects,[40] pregnant women should be encouraged to eat foods specifically higher in folic acid. Foods containing excellent to good sources of folic acid are fortified grains, spinach, lentils, chick peas, asparagus, broccoli, peas, Brussels sprouts, corn, and oranges. However, research suggests that diet alone is unlikely to provide levels similar to those from folate-multivitamin supplementation.[41]

Apples

In two birth cohort studies of children, maternal intake of apples or apple juice had a protective effect on the children, with a 40% decreased rate of wheeze and about a 50% lowered risk of asthma at age 5.[42,43] Apples have a powerful phytochemical content, which includes flavonoids, isoflavonoids, and phenolic acids. Because apple juice is a high-sugar food, whole apples are advised.

Vegetarian Diets

Although vegetarian diets are associated with healthier pregnancy weight,[44] strict vegan diets have been reported to cause low

pregnancy vitamin B_{12} status, anemia, and delayed infant development.[45] The American Dietetic Association (ADA) proffers that properly planned vegetarian or vegan diets can be "healthful, nutritionally adequate, and may provide health benefits in the prevention and treatment of certain diseases." The ADA also suggests that well-planned vegetarian diets are appropriate for individuals during all stages of the life cycle, including pregnancy and lactation.[46]

Soy

Soy is a staple in many vegetarian diets. The use of soy during pregnancy is controversial. A Danish analysis suggests that a pregnancy diet lacking fish and meat was associated with a more than fourfold increased risk of hypospadias,[47,48] possibly due to increased soy intake. Suspected estrogenic effects[49] may disrupt male masculinization through interference at the pituitary-gonadal axis.[50] Study of animal perinatal genistein exposure resulted in alterations in the male reproductive system (i.e., smaller anogenital distance and testis size, delayed preputial separation, lowered testosterone). Maternal exposure to the daidzein in rats during pregnancy had a masculinization effect on female offspring in regard to memory and social behavior.

Generations of Asian cultures have consumed soy. At this point, there is no clear evidence of reproductive damage or untoward effects in humans.[51] As a prudent measure, it may be helpful to balance soy protein with other sources of protein.

Fish

Eating fish during pregnancy can support future brain development and reduce the risk of asthma and atopy in offspring by 40%; it can also help to prevent postpartum mood disorders in the mother.[52] As a rich source of the essential long-chain n-3 (omega-3) polyunsaturated fatty acids (PUFA), fish provides structural and physiologic support for neurologic, immune, and cardiovascular system development. In pregnancy, the desired minimum intake of 200 mg docosahexaenoic acid (DHA) per day[26] can be reached with the consumption of one to two portions of sea fish per week, including oily fish such as herring and salmon.[26,53]

Unfortunately, fish contributes significantly to dietary exposure to methylmercury, dioxins and polychlorinated biphenyls, brominated flame retardants, camphechlor, and organotin.[54] Bioaccumulative contaminants tend to concentrate in larger fish.

Mercury. The greatest susceptibility to the critical contaminants methylmercury and the dioxin-like compounds occurs during early development. Methylmercury is particularly toxic to the developing brain and may also adversely affect child growth.[55-57] A woman can effectively decrease methylmercury levels in her body by reducing the intake of contaminated foods in the months prior to and during pregnancy. Compared with other foods, salmon is relatively low in mercury as well as in levels of 18 other trace metals; however, the levels are three times higher in wild salmon than in farmed. Total mercury intake from both is lower than from many other foods[58] (Box 201-3).

Dioxins. Unwanted by-products of a variety of industrial and combustion processes, dioxins have also been found in fish. Because they break down very slowly, avoiding them right before and during pregnancy will not decrease fetal exposure.

The highest levels of dioxins are found in herring, and wild/farmed salmon. The European Food Safety Authority suggests that two portions of fish per week are unlikely to exceed the tolerable weekly intake of dioxin during pregnancy. Very high levels are found in Baltic Sea fish, and should be avoided.

BOX 201-3 Mercury in Fish

High-mercury fish	Low-mercury fish
• Marlin	• Salmon (farmed has less mercury than wild)
• Pike	• Herring
• Swordfish	• Anchovies
• Shark	• Sardines
• Tuna	• Rainbow trout
• Halibut	• Calamari
• Mackeral	• Flounder
• Bass	• Tilapia
• Lobster	• Trout

Data from National Resources Defense Council. *Consumer Guide to Mercury in Fish.* http://www.nrdc.org/health/effects/mercury/guide.asp. Accessed February 15, 2012.

Polychlorinated Biphenyls (PCBs). Although PCB use ceased in the 1970s, virtually all samples of human blood, fat, or breast milk show some detectable PCBs.[59] They are found at the highest levels in fish and inorganic butter; moreover, farmed salmon contains significantly higher levels of PCBs than wild varieties of the fish. It was therefore concluded that eating farmed Atlantic salmon, "may pose health risks that detract from the beneficial effects of fish consumption."[60]

The ingestion of PCB-contaminated fish before and during pregnancy can contribute to low birth weight, small head circumference, earlier birth, a depressive response in the infant, and impaired vision and memory. At age 11, children who had been exposed to PCBs had thrice the risk of low verbal IQ and twice the lag in reading comprehension/attention issues as children who had not been so exposed.[61]

The U.S. Food and Drug Administration (FDA) and Environmental Protection Agency recommend that pregnant women and youngsters eat no more than two servings of salmon or other low-mercury fish each week.[62] However, the benefits of eating fish may outweigh the risks. It may be prudent to have pregnant women focus on fish with lower mercury and PCB content and to avoid eating the skin and fat typically found along the ventral, lateral, and abdominal areas, where PCBs are most heavily deposited.

Flaxseed

Flax is considered a good source of fiber and omega-3 fatty acids in the form of alpha-linolenic acid, and it is the richest source of the lignan secoisolariciresinol diglycoside (SDG), a phytoestrogen precursor. Flaxseed consumption during pregnancy is thought to be beneficial for fetal brain development based on its omega fat content. Because of SDG, there has been concern about the ingestion of flax during pregnancy.

Rat studies using a high percentage of dietary flax in pregnancy have shown lower birth weights, female offspring with shortened anogenital distance, greater uterine and ovarian relative weights, lighter body weight at puberty, as well as lengthened estrous cycle and persistent estrus; the males had reduced postnatal weight gain, greater sex gland and prostate relative weights, and delayed puberty.[63] An analysis of 3191 study subjects found that exposure to flax oil during the last two trimesters of pregnancy quadrupled the risk of preterm birth. The authors of this study were not clear on doses or whether the effect of flax on prematurity is explained by a phytoestrogenic effect.[64]

Caffeine

Caffeine intake, most often in the forms of coffee or black and green tea, is commonplace during pregnancy. Although rat studies using 24-cup human-equivalent doses of black tea found no changes in pregnancy outcomes,[65] a study of 1063 pregnant women who consumed 200 mg/day or more of caffeine (the amount in 10 ounces of coffee or 25 ounces of tea) revealed a doubling in the risk of early miscarriage (12.5% to 24.5%). The increased risk was associated with caffeine itself and was separated from confounders such as smoking or advanced maternal age.[66] An 8-year analysis of 3346 case infants and 6642 controls found no teratogenic consequences of maternal caffeine intake.[67,68]

Cocoa/Theobromines[69]

Having increased in per capita intake over the last four decades, cocoa and chocolate have enjoyed popularity and perceived health benefit with little pregnancy outcome information. One large study has nonconclusively suggested that maternal prenatal intake of cocoa could be associated with both hypospadias and testicular cancer in male offspring. Moreover, a study comprising a 2291-woman cohort found that theobromine concentrations in cord serum from five or more servings of chocolate was inversely associated with preeclampsia when compared with women who consumed less than one serving of chocolate weekly.[70] Another study found no correlation.[71]

Stevia

Stevia is a small perennial shrub that yields a white crystalline compound (stevioside) commonly used as a natural sweetener. With no calories, it is over 100 to 300 times as sweet as table sugar. Animal studies suggest no effect on growth or reproduction.[72-74] Although no human trials are available, the FDA rates stevia as generally recognized as safe (GRAS).

Peanuts

About 1% of the population reports peanut or tree nut allergy.[75] Studies have found that the babies of mothers who ate a greater number of peanut products during pregnancy were more likely to test positive for peanut allergies (showing up as allergic factors in the blood).[76] What is particularly interesting in this study is that all sensitized infants also tended to have either milk or egg allergy and/or significant eczema. It is possible that this underlying inflammatory response may cause increased reactivity to peanut. Although not conclusively known, maternal peanut consumption during pregnancy may accelerate child peanut sensitization.

Sleep

Anecdotally thought of as a 'preparation for life with the newborn," interrupted sleep during pregnancy is a challenge to the health of the mother-to-be as well as to her expected child. Pregnancy itself will also affect the quality of sleep, with difficulty in assuming the usual sleep positions, discomfort from fetal movements, cramps, and poor sleep quality, with the latter being influenced by the previous complaints. Pregnancy is associated with some specific sleep disorders, such as obstructive sleep apnea and restless legs syndrome. Decreases rapid-eye-movement sleep during the last trimester can be explained by progesterone and estrogen alterations.[77]

Animal pregnancy studies show that sleep deprivation affects child renal development negatively.[78] Human sleep deprivation (less than 8 hours per day) during pregnancy risks a 3.8 times increase in first-trimester miscarriage,[79] impairs the mother–infant relationship, and promotes postpartum depression.[80]

TABLE 201-2 **Recommendations for Exercise During Pregnancy**

AGENCY	RECOMMENDATIONS
ACOG	• Not recommended if a woman has risk factors for preterm labor, vaginal bleeding or premature rupture of membranes. • Safe exercises, even for women who do not exercise before pregnancy, include walking, swimming, cycling, and aerobics. • In women who are active before pregnancy, running, racquet sports, and strength training may be safe to continue in moderation. • Skiing, contact sports, and scuba diving should be avoided. • If just beginning to exercise, women should start with 5 minutes of exercise a day and add 5 minutes each week until 30 minutes of activity a day is tolerable. • Avoid exercises that require lying prone after the first trimester and exercises that may cause overheating or dehydration.
DH-UK	• If inactive before pregnancy, do not suddenly start strenuous exercise. • Keep active on a daily basis. Half an hour of activities a day, such as walking, keeping in mind that any amount is better than nothing. • Avoid strenuous exercise in hot weather. • If attending exercise classes, ensure the instructor is qualified and aware of the pregnancy and gestational age. • Swimming will support increased weight, and many pools offer aquanatal classes.
HHS-US	• Healthy women not already highly active or doing vigorous-intensity activity should get at least 150 minutes (divided) of moderate-intensity aerobic activity per week during pregnancy and the postpartum period. • Pregnant women who habitually engage in vigorous-intensity aerobic activity or are highly active can continue physical activity during pregnancy and the postpartum period provided that they remain healthy and discuss activity adjustment with a health practitioner.

Recommendations based on the following:

Yonkers KA, Wisner KL, Stewart DE, et al. The management of depression during pregnancy: a report from the American Psychiatric Association and the American College of Obstetricians and Gynecologists. *Gen Hosp Psychiatry* 2009;31(5):403-413.

American College of Obstetricians and Gynecologists (ACOG). *Exercise during Pregnancy.* American College of Obstetricians and Gynecologists, Washington, DC; 2003.

Department of Health (DH-UK): *The Pregnancy Book 2007*. London: Department of Health; 2007.

U.S. Department of Health and Human Services (HHS-US). *2008 Physical Activity Guidelines for Americans*. Washington, DC: U.S. Department of Health and Human Services; 2008.

Exercise

Recommended by all major health departments as well as the American College of Obstetricians and Gynecologists (ACOG), the Department of Health, and the U.S. Department of Health and Human Services, exercise during pregnancy has shown improvement in positive well-being, moderate effects on psychological distress, a large reduction of fatigue in the second trimester,[81] as well as lower miscarriage[79] and depression risk[82] (Table 201-2).

Commonsense physical activity recommendations include avoiding contact sports, engaging in low-impact activities,

wearing an athletic support bra, drinking ample water, and eating a snack 30 minutes before exercise to assure adequate blood sugar levels.

Pregnant women may have to avoid exercise if there is high or malignant blood pressure, asthma, or a threat of miscarriage.

Studies suggest that regular exercise during pregnancy can have a positive effect on a baby's birth weight without putting the pregnancy or child at risk. Regular exercise was associated with lower birth weights (within the normal range) and reduced cord concentrations of growth-related peptides, suggesting an influence of exercise on endocrine regulation of fetal growth.[83]

One interesting case of exercise during pregnancy is that of Paula Radcliffe, an English champion long-distance runner. Ms. Radcliffe ran throughout her pregnancy, avoiding heart rates above 160 beats per minute, and she agreed to uterine imaging every month after month five. For the first 5 months, she ran twice a day, 75 minutes in the morning and 30 to 45 minutes in the evening. After month 5, she ran 1 hour in the morning and then used a stationary bike at night. She ran up to the day before she gave birth to a healthy baby. Twelve days after her daughter's birth, she started running again.[84]

Alcohol

Fetal alcohol syndrome is the leading cause of mental retardation in the United States. Sources suggest that earlier gestational exposure to alcohol, often during the time before a woman has become aware of her pregnancy, may be most detrimental. According to studies, 60.2% of women said they did not drink during their pregnancies, and 25.9%, 5.5%, and 2.5% were categorized as light, moderate, and heavy/binge drinkers, respectively.[85] Social factors such as being single or divorced, and intimate partner violence increased alcohol consumption risk.[86]

The Millennium Cohort Study of 11,513 children born in the United Kingdom between September 2000 and January 2002 found that by limiting alcoholic beverages during pregnancy to one or two per week, the resulting offspring were 30% less likely to have behavioral problems at age 5. Cognitive testing showed no behavioral or cognitive deficits. The authors cautioned that this observational study focused on light drinkers and there is still no precedent that any level of alcohol consumption is safe, because the long-term effects are unknown.

Smoking

Smoking during pregnancy is among the leading preventable causes of adverse maternal and fetal outcomes.[87] About 37% of women smoke before becoming pregnant, and 27% continue to do so during their pregnancies. Pregnancy smoking leads to fetal growth restriction, retroplacental hematoma, increased preterm birth, shorter fetal crown-to-rump lengths, placenta previa, and death in utero.[88,89] Smoking cessation is an important goal for the woman thinking about pregnancy, and it is urgent in pregnant women.[90]

Cannabis

Cannabis is the most frequently used illicit drug among pregnant women, and prenatal cannabis exposure is associated with fetal growth restriction, decreased birth weight, reduced length, smaller head circumference, and newborn cognitive, motor, and emotional issues.[91-93] Increases in offsprings' later tobacco use and adolescent psychosis have also been noted.[94]

Betel Nut

The fourth most commonly used drug in the world after tobacco, alcohol, and caffeine is the betel nut. It is the seed of the Areca palm, which grows in much of the tropical Pacific, Asia, and parts of east Africa. It is customarily wrapped in betel leaves and chewed. In Taiwan, 23.7% of aboriginal women were found to have chewed betel during pregnancy versus almost no nonaboriginals.[95] Studies in mice have shown that betel alkaloids cause skeletal immaturity,[96] and cases of human newborns showing withdrawal symptoms are documented.[97]

Stress and Mind-Body Modalities

High stress triples the risk of pregnancy hypertension, causes adverse birth outcomes, and doubles preterm delivery risk.[98] Whereas low and moderate anxiety in the first or early second trimester did not significantly affect birth outcomes,[99] anxiety in the second and third trimesters is linked to smaller infant size, lower Apgar scores, increased obstetric complications, lower birth weight, and shorter birth length, after adjustment for confounders, as well as shortened gestational age.[100,101]

Stress during pregnancy also alters regulation of the fetal hypothalamic-pituitary-adrenal (HPA) axis,[102-105] with altered hippocampal glucocorticoid receptor density and sensitivity. Maternal anxiety or depression during pregnancy is linked with HPA axis overreactivity and higher cortisol in infants and children.[106-108] Impaired functioning of the HPA axis is associated with metabolic syndrome,[109] fibromyalgia, depression,[110] and posttraumatic stress disorder[111,112] and likely increases the susceptibility of offspring to stress-related disorders.

Mind-body modalities may hold the greatest promise in balancing HPA axis function. There is evidence that pregnant women benefit from mind-body therapies used in conjunction with conventional prenatal care. In a meta-analysis, progressive muscle relaxation was the most common intervention used in pregnant women. Other studies used a multimodal psychoeducation approach or a yoga/meditation intervention and found modest evidence for the efficacy of mind-body modalities during pregnancy. Treatment group outcomes included healthier birth weight, shorter labor, fewer instrument-assisted births, and reduced perceived stress and anxiety.[113]

Sunlight

Several studies have shown that the month of birth can affect the birth weight and height of children. The mechanism of this phenomenon is not fully explained, but the importance of hours of sunlight may play a role. An evaluation of 10,631 neonates found that higher temperature, more hours of sunlight, greater rainfall, and lower humidity are associated with greater birth length.[114] Prenatal sunlight is one of the most significant determinants of height.[115] These findings signify that better nutrition and more active lifestyles of pregnant women, with a longer warm period, may have beneficial outcomes.

Conversely, diseases in offspring may be encouraged by minimal sun exposure. An Australian study reports that low maternal exposure to sunlight during the first trimester of pregnancy may increase the risk of offspring later developing multiple sclerosis.[116] Other autoimmune diseases may also play a role this relationship.

A likely factor in sunlight benefit is the role of vitamin D for both healthy pregnancies and healthy offspring. Pregnancy is a vulnerable time for vitamin D deficiency because of increased

physiologic needs and reduced maternal outdoor activity.[117] Although there are some vitamin D–rich foods, their benefit is minimal in comparison with sun exposure. The importance of vitamin D in pregnancy is discussed further later in this chapter.

Environmental Toxins

Earlier in this chapter, mercury and PCBs from fish were discussed.

Generally, most pregnant women take elaborate steps to protect their babies' health by avoiding alcohol, caffeine, tobacco, and sometimes even soft cheeses and deli meats. In spite of these efforts, studies report that the typical pregnant woman has dozens of potentially toxic or even cancer-causing chemicals in her body, including ingredients from flame retardants and rocket fuel.

Environmental factors are known to trigger epigenetic changes in the fetus, which may not manifest until years later. For example, spray-cleaning products have been associated with wheezing and impaired lung function in children up to 8.5 years of age.[118] Environmental pollutants may trigger genetic changes that can affect a person's health and that, in some cases, may be passed on to future generations.

One CDC study of 268 women showed detectable levels of eight types of chemicals in their blood or urine, and many of these agents pass easily through the placenta to concentrate in the fetus. Included were pesticides, flame retardants, perfluorocarbons used in nonstick cookware, phthalates, pollution from car exhaust, perchlorate, and PCBs.[119] Other studies have found these chemicals in babies' umbilical cords.

Pthalates/BPA

The FDA has expressed "some concern" that bisphenol A (BPA), an estrogen-like industrial petrochemical found in 96% of pregnant women, affects the brain, prostate, and behavioral development in children exposed both before and after birth. In one study, 9 of 10 randomly selected samples of cord blood tested positive for BPA.[120] Phthalate exposure during childhood was associated with attention deficit hyperactivity disorder (ADHD) in a cross-sectional study of Korean children between the ages of 8 and 11 years.[121]

Pthalates are found in plastics, solvents, antifoam agents, alcohol denaturants, vinyl flooring, wall covering, pesticides, and personal care products (fragrances, shampoos, cosmetics, and nail polish). Human exposure occurs through inhalation, ingestion, and dermal contact.[122]

A 4-year evaluation of prenatal phthalate exposure in 404 subjects in New York City found increased concentrations of phthalate metabolites associated with poorer scores on aggression, conduct, attention, and emotional control, especially among boys. Prenatal pthalate exposure likely plays a role in children clinically diagnosed with conduct disorders or ADHD.[123] Pregnant women should avoid phthalates as much as possible.

Cell Phone Radiation

There is some evidence regarding prenatal and postnatal exposure to cell phone use and behavioral problems in children.[124] An evaluation of mothers of 13,159 children reported almost twice the incidence of behavioral problems in children who had possible prenatal or postnatal cell phone exposure. More studies are needed, but it may be prudent to reduce such exposure by following Newton's law of radiation; that is, by increasing distance. Speakerphones may be of benefit here.

Arsenic and Perchlorates

Arsenic is poisonous to any organism, and arsenic exposure during pregnancy (in tested as concentrations of metabolites of inorganic arsenic in maternal urine samples) was associated with increased morbidity due to infectious diseases during infancy.[125] Perchlorate in drinking water during pregnancy was assessed in 497,458 newborns in California; the results suggest that higher perchlorate levels are associated with higher-than-normal neonatal TSH levels.[126] Water filters can prevent exposure.

Lead

Higher maternal lead levels can lead to complications such as preeclampsia or eclampsia, potentially deadly seizures that can also increase a woman's future risk of heart attack as well as cognitive deficits in her infant.[127] Maternal tibial-patellar lead levels suggest that the genomic methylation of the developing fetus can be influenced by maternal cumulative lead burden, which may influence long-term epigenetic programming and disease susceptibility.[128]

Air Pollution

Both outdoor and indoor air pollution may play a role in pregnancy and the health of offspring.

Air pollution can affect fetal health through direct effects on the fetus via placental exposure and by effects on the mother's health.

Inconclusive studies of exposure to traffic-related airborne pollutants have been associated with an array of health effects, including pulmonary and cardiovascular challenges, asthma, low birth weight, and preterm delivery.[129,130] Like maternal smoking, air pollution may encourage premature rupture of membranes, placental abruption, and lower birth weight.

Indoor air pollutants are likely a stronger player in pregnancy health. Indoor air studies have looked at thousands of South Asian, African, and Latin American women who were commonly exposed to indoor air pollutants such as smoke secondary to third-world cooking fuels. Among such women, poorer pregnancy outcomes and correlations with stillbirth were found as compared with women who cooked with cleaner fuels.[79] Indoor air quality can be improved by improving choices in cooking, cleaning products, paint, furniture, carpeting, and anything brought into the home. Also, the use of air filters that can filter particulate matter as well as chemicals, volatile compounds, and solvents is recommended.

GENERAL SUPPLEMENTATION

Although the research is scant, one study suggests that about 62% of pregnant women use supplements (Box 201-4). They tend to rely on friends and relatives for advice in deciding to use these. A British study reports that dietary supplement use during

BOX 201-4 Supplements Used During Pregnancy

Folate: 70%
Iron: 38%
Multivitamin: 27%
Ginger: 7% to 20%
Echinacea: 8%
Raspberry leaf/pregnancy tea: 8% to 9%

Data from Patterns of vitamin, mineral and herbal supplement use prior to and during pregnancy. *Aust N Z J Obstet Gynaecol* 2002;42(5):494-496.
Maats FH, Crowther CA. *Am J Obstet Gynecol* 2001;185(2):433-437.
Tsui B, Dennehy CE, Tsourounis C. A survey of dietary supplement use during pregnancy at an academic medical center. Am J Obstet Gynecol. 2001 Aug;185(2):433-7.

pregnancy declined from 82% of women in the first trimester of pregnancy to 22% in the second trimester and 33% in the third trimester.[131]

Multivitamins and Folic Acid

A 2008 review of medline, PubMed, and Cochrane databases found that the use of folic acid and a multivitamin supplement among women of reproductive age reduced the incidence of birth defects (anencephaly, myelomeningocele, meningocele, oral facial cleft, structural heart disease, limb defect, urinary tract anomaly, hydrocephalus).[41] With concerns about folic acid masking a vitamin B_{12} deficiency, this study concluded that 5 mg of folic acid supplementation will not mask a vitamin B_{12} deficiency (pernicious anemia).

Excellent sources of folate are spinach, asparagus, romaine lettuce, turnip greens, mustard greens, calf's liver, collard greens, cauliflower, broccoli, parsley, lentils, and beets.[132] This study, however, points out that it is unlikely that diet alone can provide levels similar to those obtained from folate-multivitamin supplementation, because nutrient densities in foods are poor. A study by the ADA—comprising over 70 dietary analyses of 20 different diets from a cross section of people, including athletes and sedentary people—showed that all diets including food alone fell short of the recommended daily allowance (RDA) of micronutrients. Even more, it was shown that the more active the person, the greater the tendency toward deficiency.[133] Pregnancy is clearly a condition of increased nutrient need; therefore, a multivitamin seems to make sense.

Folate is particularly important in the synthesis of purines and pyrimidines, in the conversion of homocysteine to methionine, and in the interconversion of serine and glycine.[134,135] Prenatal folate deficiency may influence the risk of schizophrenia in offspring by inhibiting optimal neurogenesis and allowing homocysteine to accumulate in the fetal brain.[34,136]

A folate-supplemented diet with additional daily supplementation of multivitamins with 5 mg of folic acid should begin at least 3 months before conception and continue until 10 to 12 weeks postconception. From 12 weeks postconception and continuing throughout pregnancy and the postpartum period (4 to 6 weeks or as long as breastfeeding continues), supplementation should consist of a multivitamin with folic acid (0.4 to 1.0 mg).

The form of folic acid may also play a role in efficacy. According to some studies, metabolism of folic acid into its form 5-methyltetrahydrofolate may be impeded, and up to half of women may have this difficulty due to common genetic mutations.[137] As such, L-methylfolate forms of this nutrient may be more efficacious.

Three patient scenarios with specific folic acid recommendations are as follows[138]:

1. Patients with no personal health risks, planned pregnancy, and good compliance:
 - Folate-rich diet
 - Multivitamin with folic acid (0.4 to 1.0 mg) daily for at least 2 to 3 months before conception and throughout pregnancy and postpartum period (4-6 weeks and through breastfeeding)
2. Patients with health risks, including epilepsy, insulin-dependent diabetes, obesity (BMI >35 kg/m^2), family history of neural tube defect:
 - Increased folate-rich foods
 - Multivitamins with 5 mg of folic acid daily, beginning at least 3 months before conception and continuing until 10 to 12 weeks postconception. From 12 weeks postconception and continuing throughout pregnancy and the postpartum period (4 to 6 weeks and through breastfeeding) a multivitamin with folic acid (0.4-1.0 mg) daily
3. Medicated patients with a poor compliance history as well as poor diet, no consistent birth control, and teratogenic substance use (alcohol, tobacco, recreational nonprescription drugs):
 - Counseling regarding prevention of birth defects and health problems
 - Folic acid (5 mg) with a multivitamin daily

Essential Fatty Acids

The benefits of EFAs are numerous, as previously discussed in regard to fish intake. Essential omega-3 polyunsaturated fatty acids (PUFAs) are critical during pregnancy and must be obtained through diet.

DHA is a necessary structural component of the brain and retina, with uptake maximal during the second half of gestation and infancy.[139] It is known that preterm infants have delayed mental development, likely because the third trimester is a period of rapid brain growth and development that requires DHA for brain cell structure and communication.[140] National nutritional surveys have shown that the average intake of DHA during the last trimester of pregnancy is between zero and 100 mg,[141] with 90% of women well below the minimal recommendation of 300 mg a day and the United States having the third lowest intake of DHA in the world.[151]

In totality, clinical studies support the use of fish oil in pregnancy. Two recent independent meta-analyses reveal that omega-3 fats healthfully prolonged gestation by a mean of 1.6 or 2.6 days, accompanied by a slight increase in birth weight (of 47 or 54 g) and reduced the risk of preterm birth before 34 weeks of gestation by 31% in normal pregnancies and by 61% in high-risk pregnancies.

A recent double-blind multicenter randomized controlled trial of 2399 women found that those who took fish oil supplements also enjoyed a significantly lower risk of very preterm birth (defined as delivery before 34 weeks' gestation) than did women in the control group. The rate of very preterm birth was 1.1% with DHA-rich supplements (13 such births) compared with 2.3% with placebo (27 such births). The downstream benefits of that difference included lower rates of low birth weight, fewer admissions to the neonatal intensive care unit, and a nonsignificant 30% reduction in infant mortality. Interestingly, 64% of the women who were initially screened but ineligible to take part in the trial were excluded because they were already taking prenatal supplements containing DHA. It is possible that earlier intervention with fish oil might have yielded even better results. Possibly, supplementation with higher levels of eicosapentaenoic acid (EPA) relative to 800 mg of DHA, as found in nature, might also have improved benefits. However, no effect was seen on postpartum depression or cognitive and language development in the offspring during early childhood. Dosages of 800 mg/day of DHA and 100 mg/day of EPA may have been low in EPA for emotive or cognitive benefit.[142]

In regard to dosing, pregnant women should aim to achieve a minimum 300 mg/day of DHA. Intakes of up to 1 g of DHA or 2.7 g/day of total omega-3 long-chain fatty acids have been used in randomized clinical trials without significant adverse effects.[26] Fish in various doses and fish oil capsules in doses ranging from 0.1 to 2.8 g, from weeks 17 to 27 of gestation until delivery, showed no increase in spontaneous deliveries versus the control group.[143]

Fish oil supplementation may be a healthier source of fatty acids than fish because of environmental toxins, which can easily be removed from fish oil.[144,145] Except for some reported discomfort such as belching and unpleasant taste, no adverse effects have been detected up to the highest intake of 2.8 g of total omega-3 fats.

Although vegetable oils contain varying levels of healthy fats, the conversion from the parent omega-3 PUFA, alpha-linolenic acid, to the more biologically active long-chain omega-3 PUFAs, DHA and EPA, is inefficient. Therefore, fish oils are likely a better choice than plant oils.[146]

Evening Primrose Oil (EPO)

EPO is rich in omega-6, containing both linoleic acid (LA) and gamma linolenic acid (GLA). Pregnant rats given alcohol and EPO found a significant reduction in the embryopathic activity of ethanol. Chronic ethanol intake causes a depletion of EFAs. It is possible that in pregnant women who consume excess alcohol and will not cease that intake, EPO may be protective by reducing alcohol's teratogenic potential.[147]

Anecdotal reports suggest that EPO may hasten cervical ripening, shorten labor, and decrease the postdate pregnancy likelihood. One study supplementing from the thirty-seventh gestational week until birth does not support this.[148] Although EPO is rated as GRAS, the use of orally administered EPO may be associated with an increase in the incidence of prolonged rupture of membranes, oxytocin augmentation, arrest of descent, and vacuum extraction.[149] Therefore, it is not recommended except in the case of alcohol intake with pregnancy.

Vitamin D

Although it was thought in the 1960s to cause fetal heart defects, mental disabilities, and elflike facial features, recent genetic studies have identified the cause as Williams syndrome, a rare genetic deletion disorder affecting vitamin D metabolism.[150]

Vitamin D is a preprohormone that supports calcium homeostasis, bone health,[151] and general immune function.[152] Vitamin D plays a role in pregnancy immune tolerance, insulin resistance,[153] and preeclampsia risk.[154] The vitamin appears to increase the amount of blood flowing to the placenta, bringing more oxygen and nutrients to the fetus and promoting healthier growth.[155] The effects of inadequate vitamin D are listed in Box 201-5.

Adequate vitamin D may prevent premature delivery, offspring wheezing,[156,157] and multiple sclerosis.[116] One study comprising 494 women found that those taking 4000 IU/day of vitamin D halved their the risk of premature delivery as compared with women who took only 400 IU. Interestingly, the women taking part in this study were living in sunny Charleston, South Carolina. In this population, 85% had insufficient or "frankly deficient" vitamin D levels at study onset, which corroborates other studies of women living in sunny places.[150]

BOX 201-5 Risks of Vitamin D Deficiency

Low vitamin D in pregnancy increases the risk of:

- Adverse musculoskeletal effects
- Bacterial vaginosis
- Small-for-gestational-age babies
- Preeclampsia
- Flu

Prepregnancy obesity predicts poor vitamin D status in mothers and their neonates.[158] Serum 25(OH)D levels should be tested before pregnancy if possible as well as during early pregnancy to help decide on appropriate supplementation. Levels of 50 to 80 ng/mL would be adequate.

Magnesium

Mounting research demonstrates that low magnesium status may play a role in several pregnancy-related disorders. These include vasospasm, coagulation defects, premature delivery, hypertension and eclampsia, intrauterine growth restriction, and muscle cramping.

A meta-analysis involving 2689 women showed that oral magnesium supplementation given before the 25th week of gestation supported a 30% lower preterm birth frequency, 33% lower low-birth-weight frequency, 30% fewer small-for-gestational-age infants, and 62% fewer cases of antepartum hemorrhage compared with placebo. However, reviewers of this study concluded that poor-quality trials had led to a bias in favor of magnesium supplementation.[159]

Low protein intake will negatively affect magnesium absorption. Studies report that protein intakes of more than 0.4 g/kg of body weight resulted in a magnesium absorption of more than 40%. And a protein intake of 0.36 g/kg of body weight resulted in a magnesium absorption of 28%.[160] The magnesium intake of pregnant women must be increased by either dietary means or supplements, especially among low-income women in soft-water states. Excessive intakes of calcium and phosphorus may be detrimental to magnesium absorption.[161]

Vitamin A

According to the WHO, vitamin A deficiency affects 19 million pregnant women worldwide, and supplementation can reduce infant mortality in regions where this micronutrient deficiency is common (with Africa and Southeast Asian countries affected the most).[162,163] Retinol (vitamin A) and other retinoids are essential nutrients required by the early embryo and fetus for gene expression, cell differentiation, proliferation, and migration.[164] Vitamin A is important in regulating early lung development and alveolar formation and to prevent night blindness.[165] Because it is important for central nervous system (CNS) morphogenesis, inadequate vitamin A can cause hydrocephalus, anencephaly, spina bifida,[166,167] and an underdeveloped posterior hindbrain.[168,169] As antioxidants, retinoids may also help to protect the developing brain from a number of potential insults that generate free radicals.[170]

Because hypovitaminosis can contribute to problems, excess vitamin A has potent teratogenic effects and is contraindicated during pregnancy. Like thalidomide, isotretinoin and vitamin A–related acne medications are responsible for a high incidence (25%) of malformations of the CNS, heart, and thymus as well as craniofacial defects.[171] The risk of birth defects owing to supplements containing a synthetic vitamin A analogue has already been documented in humans, and recently the ingestion of excess vitamin A (25,000 IU or more) as retinol/retinyl esters during pregnancy has been associated with some birth defects in a small number of case reports, although it is not known that the relationship is causal.[172]

The National Research Council's recommended dietary allowance for vitamin A during pregnancy is 1000 retinol equivalents per day, which is equivalent to 3300 IU as retinol or 5000 IU of

vitamin A obtained from the typical American diet as a combination of retinol and carotenoids (e.g., beta-carotene). An average balanced diet contains approximately 7000 to 8000 IU of vitamin A derived from different sources. The RDA established by the FDA is 8000 IU/day. Supplementation of 8000 IU of vitamin A (as retinol/retinyl esters) per day should be considered the recommended maximum prior to or during pregnancy. Beta-carotene is not metabolized or stored in the same way as vitamin A, has not been associated with vitamin A toxicity in animals or humans, but may not have the ability to prevent deficiency issues because of differences in absorption and metabolism.[173,174]

Antioxidants

Oxidative stress has been implicated in many pathologic processes during pregnancy, childbirth, and the postnatal period but the possible preventive or therapeutic effects of antioxidants remain unclear.[175,176] Overt deficiency of antioxidant status is a detriment to pregnancy. In a Ugandan rural cohort, 400 mg of vitamin C allowed 42.2% of women in the vitamin C group to avoid pregnancy hospitalization compared with 27.9% in the control group.

Beneficial effects have been seen regarding maternal vitamin E intake in respect to wheezing in the second year of life.[177] Beneficial associations have also been found between maternal zinc intake[178] during pregnancy and asthma and eczema in children at the age of 5 years. Forty milligrams of zinc gluconate effectively increased mean birth weight among anemic and iron-deficient women but not among women with elevated iron stores in early pregnancy.

Pre-2005 studies involving 6082 women suggest that supplementation of one or more antioxidants was associated with a 39% reduction in the risk of preeclampsia and a 35% risk reduction of having a small-for-gestational-age infant.[179] However, two more recent trials, with supplementation of high dosages of both vitamins C and E, did not show any reduction of preeclampsia. In one of these trials, supplementation with vitamins C and E was associated with a significantly higher rate of low-birth-weight infants.[180,181]

Overall, the currently available data[182-186] do not provide a basis for recommending antioxidant intakes for pregnant and lactating women in excess of reference nutrient intakes. Women with risk factors for preeclampsia may consider additional low-dose antioxidant support.

Iron

During pregnancy, low iron and anemia can compromise oxygen delivery to the developing fetus.[187] Factors associated with deficiency include poor fetal brain and intrauterine development, prematurity, and low birth weight.[188] These lead to a poor growth trajectory in infancy, childhood, and adolescence and low adult height. Indirect indicators of fetal hypoxia have been associated with increased susceptibility to schizophrenia,[189] in which the hippocampus is believed to be particularly vulnerable to hypoxic insult.

Studies in India, where iron deficiency is the highest in the world, show that anemia is directly or indirectly responsible for 40% of maternal deaths in that country, with an 8- to 10-fold increase in morbidity and mortality rates when the hemoglobin falls below 5 g/dL.

Iron is an important component of any prenatal vitamin. A dose between 30 and 60 mg of elemental iron is common but may not be enough to prevent gestational anemia.[190]

Probiotics

The newborn gut is first colonized by microbes picked up from the mother as the baby moves through the birth canal[191]; however, this is minimized with delivery by cesarean section. Newborns delivered in this way go on to have higher rates of celiac disease.[192]

Strain of bacterium used is important to its effectiveness. *Lactobacillus* GG dosing twice daily neither reduced the incidence or severity of atopic dermatitis but was associated with increased wheezing bronchitis.[193] In a second study, pregnant mothers who were carrying infants at high risk for allergy received a mixture of four probiotic species (*Lactobacillus rhamnosus* GG and LC705, *Bifidobacterium breve*, and *Propionibacterium freudenreichii* ssp *shermanii*) 4 weeks before delivery. As a result, antibiotics were prescribed slightly less often and there were less frequent respiratory infections.[194]

Oral and intravaginal yogurt and probiotics have also been used to amelioriate bacterial vaginosis in pregnant patients. Such treatment may be a first choice in pregnant patients seeking to avoid antibiotic treatment.[195]

Probiotics seem quite safe during pregnancy, with no increased neonatal morbidity, feeding-related difficulties (such as infantile colic), or serious adverse events. A 1505-patient meta-analysis of *Lactobacillus* and/or *Bifidobacterium* found no malformations and no adverse effects on the incidence of cesarean section, birth weight, or gestational age. The safety of *Saccharomyces* during pregnancy is unknown.[196]

Choline

The rapid rate of cell division during pregnancy, the expansion of the maternal kidneys and uterus, the growth of placental and fetal tissue, as well as the increased lipoprotein required for nervous system development all deplete choline stores. Higher levels of blood choline are associated with a 2.5-fold reduction in the risk for neural tube birth defects.[197] Third-trimester fetal organ growth is extremely rapid and large amounts of choline are required for membrane biosynthesis, because neonates have choline levels three times higher than those in maternal blood.

Most pregnant women are not getting enough choline and certain genetic variants may increase requirements further. The recommended intake is 450 mg/day during pregnancy.[198] Because choline is not found in most varieties of prenatal vitamins, the focus should be on choline-rich foods (Table 201-3). Studies of choline supplementation in pregnancy are not available.

TABLE 201-3 **Dietary Sources of Choline**

FOOD	MILLIGRAMS OF CHOLINE
Egg, large[226]	115
Beef steak, 3 oz	110
Salmon, 3 oz	100
Baked beans, 1 c	70
Navy beans, 1 c	60
Brussel sprouts, 1 c	60
Kidney beans, 1 c	60
Broccoli cooked, 1 c	60

Data from Caudill MA. Pre- and postnatal health: evidence of increased choline needs. *J Am Diet Assoc* 2010;110(8):1198-1206.

Carnitine

Carnitine is an essential constituent of intermediary metabolism, and the total plasma carnitine level in nonpregnant fertile women averages around 40 µmol/L.[199] During gestation, plasma carnitine concentrations decrease precipitously. By delivery, they may be at 15 µmol/L,[200,201] a level also found in carnitine-deficient individuals.[202] It is unclear whether low carnitine in pregnant women has adverse effects on their metabolism or on the metabolism of the fetus.[203]

Plasma carnitine reduction in pregnancy is safely prevented by supplementation with 500 mg of L-carnitine L-tartrate from week 13 of gestation to term. A study of 26 women found that supplementation prevented reductions in plasma carnitine versus placebo.[204] Some evidence suggests that infant diets may have to supply supplemental carnitine to satisfy the neonate's metabolic needs.[205] L-carnitine supplementation during pregnancy may help to prevent the development of gestational diabetes, especially in overweight women, by decreasing elevated free fatty acids. Lower L-carnitine downregulates the expression of enzymes involved in fatty acid metabolism. A daily supplement containing 2 g of L-carnitine in over 80 pregnant women starting in the twentieth week increased the relative mRNA levels of these enzymes.[206]

Meat, poultry, fish, and dairy products are the richest sources of L-carnitine, whereas fruits, vegetables, and grains contain relatively little L-carnitine.

Botanicals

As in the general population, the use of botanicals in pregnancy is increasing. One midwife review of 578 expectants who were at least 20 weeks pregnant found that 60% used herbals.[207] A 2010 obstetric analysis of 4239 women who delivered infants without major birth defects found that about 10.9% reported use of an herbal product 3 months before or during pregnancy.[208] Herbal use was highest during the first trimester (6.9%), with substantial second- (5.1%) and third- (5.2%) trimester use. This study extrapolated that about 9.4%, or an estimated 395,000 births, involved antenatal exposure to at least one herbal product.

Studies show ginger as the most used, followed by cranberry, raspberry leaf, chamomile, peppermint, and *Echinacea*. Herbal teas and chamomile were most commonly used in later pregnancy. Other commonly used herbals were mint or peppermint and primrose oil. It is clear by comparing these studies that the population of women who use midwives skew toward greater use of botanicals.

Raspberry Leaf (Rubus idaeus)

Used since the sixth century, the raspberry leaf plant is "the best known and oldest of all the herb infusions and [is] included as a proved aid in maternity in the most ancient of herbal books."[209]

Feline intravenous experimentation from the 1940s found that raspberry leaf extract had a relaxant effect on the uterine musculature.[210] A retrospective Australian comparison study of 109 women showed safety, with first stage labor being shorter, as were the second and third stages. There was one preterm labor and birth in the control group compared with none in the treatment group. The percentage of normal births in the raspberry leaf group (77.2%) was slightly higher than that in the control group (66.7%).[211]

A second 192-woman study dosed 1.2 g twice daily of raspberry leaf from 32 weeks gestation until labor; it found no adverse effects for mother or baby. However, raspberry leaf did not shorten the first stage of labor, although it did shorten the second stage by an average of 9.59 minutes, accompanying a higher rate of vaginal deliveries and less use of forceps between the treatment group and the control group (19.3% vs. 30.4%).[212] Less intervention means a reduction in midwifery and medical time in labor and an increase in maternal satisfaction.[213] To allay concern that raspberry leaf may cause preterm labor and birth, it should be noted that the study of gestation lengths was similar.

Common complaints of nausea, vomiting, and diarrhea were equally distributed between the two groups. Four constipation reports were the only raspberry-exclusive complaints. Although common in pregnancy,[214-216] constipation may also be attributed to the astringent raspberry leaf.[217]

Glycyrrhiza glabra (Licorice)

Known for its hepatoprotective and pulmonary support, licorice has been studied in pregnancy. Although there is no effect on maternal blood pressure or birth weight at the high exposure of 500 mg glycyrrhizin per week,[218] children show more behavioral problems, poor attention spans, and symptoms of ADHD in a dose-dependent manner.[219]

Salivary cortisol tests show higher offspring cortisol levels as well.[220] Glycyrrhizin is a natural licorice constituent that potently inhibits 11β-hydroxysteroid dehydrogenase type 2. This enzyme blocks the fetus from receiving maternal cortisol. Using licorice can induce higher cortisol levels in utero and may alter HPA axis function in children, contributing to altered mood and stress response. Therefore, the ingestion of licorice is not recommended for pregnant women.

Gingko biloba

A murine study of ginkgo at 78 mg/kg per day (equivalent to the human dose) up to 100 mg/kg per day showed significant malformations in the eye and orbit; syndactyly; malformed pinnae, nostrils, lips, and jaws; and decreased weight as well as crown-rump length of fetuses in the 100-mg group with no change in the 78-mg or control groups.[221] A second study in pregnant rats found no embryonic death, growth restriction, or fetal malformations.[222] At this time, given the lack of human data and suggestive teratogenicity in animal data, ginkgo is not recommended during pregnancy.

Scutellaria (Scutellaria baicalensis)

There are anecdotal reports that *Scutellaria baicalensis* has some fetal calming effects. A mouse study showed higher liver and kidneys weights in the mothers who took scutellaria in high doses as compared with the controls, with dosing below 32 g/kg of scutellaria extract per day not causing significant fetal external or skeletal malformations.[223] Human research is needed.

Bitter Melon (Momordica charantia)

Well used in Asian cultures for blood sugar regulation and cancer care, bitter melon contains the abortifacient proteins trichosanthin, α-momorcharin, and β-momorcharin, which can inhibit cellular protein synthesis. The momorcharins and the ribosome-inactivating proteins isolated from bitter melon seeds have been shown to have abortifacient activity in pregnant mice.[224] The use of bitter melon during pregnancy is not recommended.

Podophyllum

This agent has historically been used to remove benign dermatologic lesions. There is a case study of a pregnant woman who used its resin topically 5 times for a duration of 4 hours each time from the 23rd to the 29th week of pregnancy in order to remove warts.

At birth, a simian crease on the left hand and a preauricular skin tag were noted on the child. It was not clear whether the topical treatment was the cause.[225]

Therapeutic Approach

Support

A midwife should be considered for optimal prenatal care, with conventional medical backup support for urgent care if needed. Psychological therapy is beneficial for those with anxiety or mood disorders.

Foods

Dietary therapies should include an organic whole-foods diet with adequate hydration and protein and seven servings of fruits and vegetables daily. Fish with toxic contaminants as well as peanuts (minimal intake), flax, and caffeinated beverages are best avoided.

Sleep

Eight hours each night.

Exercise

Daily as appropriate for the individual.

Lifestyle

Daily sunlight exposure.
Cigarettes, cannabis, and betel nuts should be avoided.
Meditation and relaxation work.
Use of filters to ensure toxin-free water and indoor air.

Nutritional Supplementation

High-quality prenatal multivitamin with 1000 to 5000 mcg of folic acid, 1000 mg of calcium, and no more than 5000 IU of vitamin A.
Essential fatty acids: 800 mg of DHA and corresponding EPA.
Vitamin D: dosed according to specific need based on laboratory findings.
Probiotic.

Botanical Medicine

According to specific health needs.

CONCLUSION

Pregnancy care is an unparalleled opportunity to improve the health of the pregnant woman as well as safeguard the childhood and adult health of the offspring by preventing disease. Natural medicine therapeutics have many options toward this goal.

DIAGNOSTIC SUMMARY

- Recurrent signs and symptoms that develop during the late luteal phase of the menstrual cycle and disappear by the end of the full flow of menses
- Symptoms typically including decreased energy, tension, irritability, depression, headache, altered sex drive, breast pain, backache, abdominal bloating, and edema of the fingers and ankles

GENERAL CONSIDERATIONS

Premenstrual syndrome (PMS) refers to the cyclic constellation of troublesome symptoms that appears during the luteal phase of the menstrual cycle—more so in the late luteal phase—disappear by the end of the full flow of menses, and do not appear during the follicular phase.[1] Although some 150 symptoms have been listed as premenstrual, the most common symptoms are as follows (Box 202-1):

- Decreased energy
- Tension
- Irritability
- Anger
- Food cravings
- Depression
- Headache
- Altered sex drive
- Breast pain
- Muscle aches
- Abdominal bloating
- Edema of the fingers and ankles

PMS is estimated to affect between 30% and 40% of menstruating women; 80% of women experience premenstrual emotional or physical changes but do not have much difficulty. Peak occurrence is among women in their 30s and 40s. In most cases symptoms are relatively mild; however, in about 2.5% to 5% of women symptoms can be severe enough to have a negative impact on their lives, putting home life and work in jeopardy. Severe PMS with depression, irritability, and severe mood swings is referred to as *premenstrual dysphoric disorder* (PMDD)[2] and has a separate diagnostic category in the fourth edition of the American Psychological Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV).

Although PMS has been a well-defined clinical entity for more than 60 years, some physicians still argue that it really does not exist.[3] Therefore, many women suffering from PMS do not receive proper treatment. Until the advent of therapy with selective serotonin reuptake inhibitors (SSRIs), conventional mainstream medicine had not been able to offer women a known cause for PMS, nor has it been able to offer satisfactory interventions. Women were by and large left to self-care or to seek the advice of alternative medicine practitioners.

The etiology of PMS has not yet been fully understood, but endocrine studies have clarified that the premenstrual symptoms are not a result of a simple excess or deficiency of any given hormone.[4] Several theories have been proposed to explain the causes of PMS; currently strongest is an interaction between the ovarian steroids and the brain's neurotransmitters. Genetic predispositions and sociocultural beliefs about menstruation may also influence what women experience. At present, the dominant thinking is that cyclic changes in the ovarian steroids estrogen and

BOX 202-1 Signs and Symptoms of Premenstrual Syndrome

Behavioral
- Nervousness, anxiety, and irritability
- Mood swings and mild to severe personality change
- Fatigue, lethargy, and depression

Gastrointestinal
- Abdominal bloating
- Diarrhea and/or constipation
- Change in appetite (usually craving of sugar)

Female
- Tender, enlarged breasts
- Uterine cramping
- Altered libido

General
- Headache
- Backache
- Acne
- Edema of fingers and ankles

progesterone cause changes in many body systems, including brain neurotransmitters, which then have emotional and physical manifestations.[5] Therefore, normal ovarian function, and not a true hormonal imbalance, triggers the central nervous system and predisposes a woman to hormone-induced instability.[6] We do not currently know why women differ in their sensitivity to the changes in ovarian steroid-induced neurotransmitters. Of the neurotransmitters studied, serotonin is the principal one implicated in the pathogenesis of PMS and PMDD.[7,8] Whether PMS and PMDD are related to absolute levels or reduced blood levels of serotonin or to serotonin transport remains unclear.[9]

Other neurotransmitter systems may also be involved in PMS and PMDD. They include the adrenergic, opioid, and gamma-aminobutyric acid (GABA) systems. Research over the last 10 to 15 years has shown that SSRIs can alleviate both the psychological and physical symptoms in most women with PMDD. Fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram, and venlafaxine have all been found to be significantly more effective than placebo for the treatment of PMDD.

DIAGNOSIS AND CLASSIFICATION

The diagnosis of PMS is usually made through the association of the symptoms attributed to PMS with their occurrence during the luteal phase of the menstrual cycle. To aid in the diagnosis, symptom questionnaires are often used. Recalled information is less accurate; therefore, so in addition to a symptom questionnaire, the patient may be asked to keep a menstrual symptom diary. This helps to document improvement as well as to further clarify the symptom pattern.

The key defining feature of both PMS and PMDD is the timing of symptoms, which appear only during the luteal phase and disappear before or during menstruation. Fundamental to making the diagnosis is to rule out other psychiatric and medical disorders. The clinician should obtain a medical and psychiatric history and be aware that many mental and physical disorders mimic premenstrual symptoms and may also coexist with them. The results of the medical, psychiatric, and psychosocial evaluations along with the symptom diary offered by the patient can help the clinician to determine whether the symptoms represent PMS or PMDD, a psychiatric or medical illness only, coexisting PMS or PMDD and another illness, or premenstrual exacerbation of an underlying psychiatric or medical illness.

Only one of the following symptoms is required for a diagnosis of PMS: mild psychological discomfort, bloating and weight gain, breast tenderness, swelling of hands and feet, various aches and pains, poor concentration, sleep disturbance, and change in appetite. The symptoms must (1) occur only in the luteal phase, (2) peak close to menstruation, and (3) subside at the onset of menses or during menstrual flow. A diagnosis of PMDD is reserved for women who have at least five of eleven specific symptoms at a severe level such that they interfere significantly with daily life and relationships and occur in the premenstrual phase of the cycle.
- Markedly depressed mood, hopelessness, self-defeating thoughts
- Marked anxiety, tension
- Feeling overwhelmed
- Marked anger, irritability
- Marked lability
- Decreased interest in usual activities
- Difficulty concentrating
- Lethargy, fatigue
- Change in appetite, food cravings
- Sleep disturbance
- Additional physical symptoms (breast tenderness, bloating, headache)

THERAPEUTIC CONSIDERATIONS

Even though it is now understood that there is no frank increase or decrease in serum estrogen or progesterone levels, a possible relative excess or insufficiency in terms of its effect on the central nervous system should still be considered. Owing to the lack of scientific understanding in this area and the clinical experience in improving estrogen metabolism in women with PMS, some clinical considerations from the past should still be recalled.

Estrogen Metabolism

In the early 1940s, Morton Biskind observed an apparent relationship between B-vitamin deficiency and PMS.[10,11] He postulated that PMS, as well as excessive menstruation and fibrocystic breast disease, was due to an excess in estrogen levels caused by decreased detoxification and elimination in the liver as a result of B-vitamin deficiency. The liver uses various B vitamins to detoxify estrogen and excrete it in the bile.

There appears to be support for Biskind's theory. Estrogen excess is known to produce *cholestasis*, a term that signifies diminished bile flow or stasis of bile. Naturopathic physicians often refer to this condition as a "sluggish liver." It reflects minimal impairment of liver function because normal indicators of liver status (such as concentrations of the liver enzymes alkaline phosphatase, serum glutamic oxaloacetic transaminase, serum glutamate pyruvate transaminase, and gamma-glutamyl-transpeptidase) are not elevated. These enzyme measurements, the conventional means of assessing liver status, are not very useful, because they serve only to indicate liver damage, being elevated only when the liver is compromised. They have little correlation with liver function. Because of the liver's important role in numerous metabolic processes, even a minor impairment of liver function can have profound effects.

Cholestasis can be caused by a large number of factors besides estrogen excess (Box 202-2). The presence of cholestasis may be a predisposing factor in PMS, because with cholestasis there is

BOX 202-2 **Causes of Cholestasis**

- Estrogen excess or birth control pills
- Pregnancy
- Presence of gallstones
- Alcohol
- Endotoxins
- Hereditary disorders such as Gilbert's syndrome
- Anabolic steroids
- Various chemicals and drugs
- Nutritional deficiencies

reduced estrogen detoxification and clearance. Hence, a positive feedback scenario is produced. The high incidence of gallstones is a clear indication that many American women suffer from cholestasis.

Again, even though elevated serum estrogen values cannot be confirmed in PMS studies, it is interesting to note that estrogen excess during the luteal phase affects endorphin levels negatively. One study found a direct correlation between an increased estrogen/progesterone ratio and endorphin activity in the brain.[12] In essence, when the estrogen/progesterone ratio was increased, there was a decline in endorphin levels. This reduction is significant considering the known ability of endorphins to normalize or improve mood. Other studies have shown that low endorphin levels during the luteal phase are common in women with PMS.[13] Endorphins are lowered by stress and raised by exercise. The role of endorphins is discussed further later.

Estrogen Impairs Vitamin B_6

The way in which estrogen levels during the luteal phase negatively affect neurotransmitter and endorphin levels may be secondary to impairment of the action of vitamin B_6. It is well known that estrogens affect vitamin B_6 function negatively. Vitamin B_6 levels are typically quite low in depressed patients, especially women taking estrogens (birth control pills or conjugated estrogens [Premarin]).[14,15] Vitamin B_6 supplementation has been shown to have positive effects on all PMS symptoms, particularly depression, in many women (discussed in greater detail later). This improvement is achieved via a combination of a reduction in midluteal estrogen levels and an increase in midluteal progesterone levels.

Dietary Considerations

Women suffering from PMS typically eat a diet that is even worse than the standard American diet. Abraham[16] reports that, compared with symptom-free women, PMS patients consume the following substances:

- 62% more refined carbohydrates
- 275% more refined sugar
- 79% more dairy products
- 78% more sodium
- 53% less iron
- 77% less manganese
- 52% less zinc

A diet that is higher in dairy products may also contribute to some PMS symptoms. A survey of 39 women with PMS and 14 women without reported that the women with PMS consumed fivefold more dairy products and threefold more refined sugar than the women without PMS.[17] Another study observed that women with PMS also have an increased intake of dietary fat, carbohydrates, and simple sugars and decreased protein intake.[18]

Food cravings are often also higher in women with PMS; this may in part be due to a decrease in serotonin during the luteal phase in PMS sufferers. Therefore, serotonergic treatments may be helpful in controlling such food cravings.[19]

Another nutritional factor in PMS is the effect of refined sugars on rapid increases in insulin, which then causes the retention of sodium and subsequent water retention, with swelling in the hands and feet, abdominal bloating, and breast engorgement. Sugar has several detrimental actions in PMS. Eating foods high in simple sugars increases insulin secretion and can be harmful to blood sugar control, especially if the patient is hypoglycemic or diabetic. Sugar, especially combined with caffeine, also has a detrimental effect on PMS and mood (discussed later).[20] A high intake of sugar also impairs estrogen metabolism. The evidence is based on the higher frequency of PMS symptoms in women consuming a high-sugar diet and the fact that a high sugar intake is also associated with higher estrogen levels.[21] One study found that a low-fat, high-complex-carbohydrate diet alleviated premenstrual breast tenderness.[22]

C-reactive protein, a marker of inflammation, has been correlated with the severity of both physical and psychological symptoms of PMS.[23] A diet that stimulates inflammatory pathways includes sugar, poultry, eggs, cheese, milk, white flour, white rice, and partially hydrogenated oils. Foods that can reduce inflammation include fresh fruits, especially berries, green leafy vegetables, fish, nuts, seeds, turmeric, garlic, and onions.

Vegetarian women have been shown to excrete two to three times more estrogen in their feces and to have 50% lower levels of free estrogen in their blood than omnivores.[24,25] These differences are thought to be due to the lower fat and higher fiber intake of the vegetarian women. These dietary differences may also explain the lower incidence of breast cancer, endometriosis, and uterine cancer in vegetarian women. They may also play a role in PMS.

At the very least, the clinician should recommend a diet lower in saturated fat and cholesterol (achieved by reducing or eliminating the consumption of animal products) and higher in fiber-rich plant foods (fruits, vegetables, grains, and legumes).

Decreasing the percentage of calories as fat, in particular saturated fat, has dramatic effects on the reduction of circulating estrogen.[26,27] In one study, when 17 women switched from the standard American diet (composed of 40% of calories as fat and only 12 g as fiber daily) to a low-fat, high-fiber diet (consisting of 25% of calories as fat and 40 g as fiber daily), there was a 36% reduction in blood estrogen levels, with 16 out of the 17 women demonstrating significant reductions in only 8 to 10 weeks.[28]

It should be noted that not all nutrition research shows a clear-cut association with PMS. In the Study of Women's Health Across the Nation, a cross-sectional analysis was conducted of PMS symptoms in a multiethnic sample of 3302 midlife women.[29]

They sought to determine if the frequency of physical or emotional premenstrual symptoms was associated with dietary intake of phytoestrogens/fiber/fat or calcium, consumption of alcohol or caffeine, cigarette exposure, lack of physical exercise, and race/ethnicity or socioeconomic status. In this study, most dietary factors were not related to PMS. Fat intake was negatively associated with craving and bloating. Fiber intake was positively associated with breast pain. Alcohol intake was negatively associated with anxiety, mood changes, and headaches. Cigarette smoke exposure, whether passive or active, was positively associated with cramps and back pain. Ethnic differences in the reporting of symptoms and comorbidity associations were observed as well.

BOX 202-3 Negative Coping Styles in Women with Premenstrual Syndrome

- Feelings of helplessness
- Overeating
- Watching too much television
- Emotional outbursts
- Overspending
- Excessive/irrational behavior
- Dependence on chemicals: drugs, legal and illicit; alcohol; cigarettes

Thyroid Function

Low thyroid function (hypothyroidism) has been shown to affect a large proportion of women with PMS.[30,31] For example, in one study, 51 of 54 subjects with PMS demonstrated low thyroid status compared with 0 of 12 in the control group.[30] In another study, 7 of 10 subjects in the PMS group had low thyroid status compared with 0 of 9 in the control group.[31] Other studies have also shown hypothyroidism to be only slightly more common in women with PMS than in controls.[32,33] Many women with PMS and confirmed hypothyroidism who are given thyroid hormone experience complete relief of symptoms.[30] For more information, see Chapter 177.

Stress, Coping Style, and Depression

Study of the interaction of stress/serotonin and PMS has shown that serotonin levels in women with PMS fall after ovulation. Those without PMS had much higher levels of serotonin during the last half of the menstrual cycle. In a holistic/natural medicine approach to PMS, the identification of stressors and stress management should not be overlooked.[34] Many women with PMS tend to employ "negative" coping styles,[35] examples of which are listed in Box 202-3. It is important to identify the manner in which the patient deals with stress and to counsel her on more positive ways of coping.

There are some important relationships between PMS and depression. Depression is a common feature in many cases of PMS, and PMS symptoms are typically more severe in depressed women.[1] The reason appears to be a decrease in the brain level of various neurotransmitters, with serotonin and GABA being the most significant.[36,37] The most common class of prescription medications recommended for moderate to severe PMS/PMDD is an SSRI. When they are used for chronic depression, SSRIs must be taken daily. When used for PMS/PMDD, they can be taken just on the days of the month when the symptoms are the most problematic. This would suggest that when used in this way, they are not really increasing neurotransmitter levels but work by altering the neurophysiology and electrical conduction in the brain. Several SSRIs have been used, including fluoxetine, sertraline, and paroxetine. However, various psychotherapy methods have been equally if not more successful in improving the psychological aspects of PMS. In particular, biofeedback and short-term individual counseling (especially cognitive therapy) have documented clinical efficacy.[38,39] One of the advantages of cognitive therapy over antidepressant drug therapy in the treatment of PMS is that learning techniques such as cognitive-behavioral coping skills can produce excellent results that are maintained over time.

Exercise

Several studies have shown that women engaged in a regular exercise program do not suffer from PMS nearly as often as sedentary women.[40-42] In one of the more thorough studies, mood and physical symptoms during the menstrual cycle were assessed in 97 women who exercised regularly and in a second group of 159 women who did not exercise.[40] Mood scores and physical symptoms assessed throughout the menstrual cycle showed significant effects of exercise on negative mood states and physical symptoms. The regular exercisers obtained significantly lower scores for impaired concentration, negative mood, behavior change, and pain.

In another study, 143 women were monitored for 5 days in each of the three phases of their cycles (midcycle, premenstrual, and menstrual).[41] The women were 35 competitive athletes, two groups of exercisers (33 high-frequency exercisers and 36 low-frequency exercisers), and 39 sedentary women. The high-frequency exercisers experienced the greater positive mood scores and sedentary women the least. The high-frequency exercisers also reported the least depression and anxiety. The differences were most apparent during the premenstrual and menstrual phases. These results are consistent with the belief that women who exercise frequently (but not competitive athletes) are protected from PMS symptoms. In particular, regular exercise protects against the deterioration of mood before and during menstruation.

These studies provide evidence that women with PMS should partake of the benefits of exercise. Exercise may reduce PMS symptoms by elevating endorphin values, improving glucose tolerance, decreasing catecholamines, and modulating estrogen levels.[43]

Nutritional Supplements

Nutritional supplements have been widely used in the treatment of PMS by alternative practitioners and most definitely by women taking things into their own hands. Despite the inconsistent evidence, the positive results do show that nutritional supplements can offer safe, affordable solutions for many problems.

Vitamin B_6

The first use of vitamin B_6 in the management of cyclic conditions in women was in the successful treatment of depression caused by birth control pills, as noted in several studies in the early 1970s. These results led researchers to try to determine the effectiveness of vitamin B_6 in relieving PMS symptoms. Since 1975 at least a dozen double-blind clinical trials have been performed. Some of these studies have shown no effect, but most of the studies have shown a significant effect on the whole range of PMS symptoms at dosage ranges from 50 to 500 mg/day.[44] For example, in one double-blind crossover trial, 84% of the subjects had a lower symptom score during the vitamin B_6 treatment period.[45] In another double-blind crossover trial, 50 mg/day of vitamin B_6 was effective in decreasing premenstrual depression, fatigue, and irritability.[46] Although PMS has multiple causes, vitamin B_6 supplementation alone appears to benefit most patients.

It is important to note, however, that not all double-blind studies of vitamin B_6 have shown a positive effect.[44,47] The negative results in some trials may have been caused by many factors, such as the inability of some women to convert vitamin B_6 to its active form owing to a deficiency in another nutrient (e.g., vitamin B_2 or magnesium) that was not supplemented. These results suggest that supplementing pyridoxine by itself may not produce adequate clinical results for all women suffering from this disorder and that some women may have difficulty converting vitamin B_6 into its active form, pyridoxal-5-phosphate. To overcome this conversion difficulty, it may be necessary to use a broader-spectrum nutritional supplement or injectable pyridoxal-5-phosphate.

For most indications, the therapeutic dosage of vitamin B_6 is 50 to 100 mg/day. This dose level is generally regarded as safe, even

for long-term use. With use of doses greater than 50 mg, it may be important to divide it into 50-mg doses taken throughout the day. A single dose of 100 mg of pyridoxine did not lead to significantly higher pyridoxal-5-phosphate levels in the blood than a 50-mg dose, possibly indicating that a 50-mg oral dose of pyridoxine is about all the liver can handle at once.[48]

Vitamin B_6 is one of the few water-soluble vitamins associated with some toxicity when taken in large doses or in moderate dosages for long periods. One-time doses larger than 2000 mg/day can produce symptoms of nerve toxicity (tingling sensations in the feet, loss of muscle coordination, and degeneration of nerve tissue) in some individuals. Long-term intake of doses larger than 500 mg a day can be toxic if taken for many months or years.[49] There are also a few rare reports of toxicity occurring at long-term dosages as low as 150 mg/day.[49-51] The toxicity is thought to occur when supplemental pyridoxine overwhelms the liver's ability to add a phosphate group to produce the active form of vitamin B_6 (pyridoxal-5-phosphate). As a result, it is speculated that pyridoxine either is toxic to the nerve cells or actually acts as an antimetabolite by binding to pyridoxal-5-phosphate receptors, thereby creating a relative deficiency of vitamin B_6. Another possibility is that minute amounts of contaminants or vitamin B_6 analogs may have been introduced during synthesis. Although not a problem at normal doses of vitamin B_6, contaminants present in larger doses may block vitamin B_6 activation sites. Again, it appears to make sense to limit doses to 50 mg at a time. If more than 50 mg/day is desired, the doses should be spread out throughout the day.

Vitamin B_6 has the ability to increase the synthesis of several neurotransmitters in the brain including serotonin, dopamine, norepinephrine, epinephrine, taurine and histamine. There are also extensive interactions between vitamin B_6 and magnesium, which work together in many enzyme systems. In fact, another mechanism by which vitamin B_6 may improve the symptoms of PMS is by increasing the accumulation of magnesium within body cells.[52] Without vitamin B_6, magnesium does not get inside the cell.

Magnesium

Magnesium deficiency has been implicated as a causative factor in PMS.[53] Red blood cell (RBC) magnesium levels in patients with PMS have been shown to be significantly lower than in normal subjects.[16,54] Because magnesium plays such an integral part in normal cell function, magnesium deficiency may account for the wide range of symptoms attributed to PMS. Furthermore, magnesium deficiency and PMS have many common features, and magnesium supplementation has been shown to be an effective treatment of PMS. In one study involving 32 women with PMS, 360 mg of magnesium three times daily was given from midcycle to the onset of menstrual flow.[55] Relief of premenstrual mood fluctuations and depression during magnesium treatment was significant.

A recent study designed to improve understanding of the association between magnesium and the menstrual cycle measured plasma, RBC, and mononuclear blood cell (MBC) magnesium concentrations in 26 women with confirmed PMS and in a control group of 19 women during the follicular, ovulatory, early luteal, and late luteal phases of the menstrual cycle.[56] Although there were no significant differences in plasma magnesium levels between PMS patients and control subjects and there was no menstrual cycle effect on plasma magnesium, women with PMS had significantly lower RBC magnesium concentrations than those in the control group, which was consistent throughout the menstrual cycle.

The observation of low RBC magnesium concentrations in patients with PMS has now been confirmed by four independent studies. In general, it is thought that women with PMS have a "vulnerability to luteal phase mood state destabilization"[56] and that chronic and enduring intracellular magnesium depletion serves as a major predisposing factor for destabilization.

In addition to emotional instability, magnesium deficiency in PMS is characterized by excessive nervous sensitivity with generalized aches and pains and a lower premenstrual pain threshold. One clinical trial of magnesium in PMS showed a reduction of nervousness in 89%, breast tenderness in 96%, and weight gain in 95% of subjects.[16] In another double-blind study, high-dose magnesium supplementation (360 mg three times daily) was shown to dramatically relieve PMS-related mood changes.[55]

Although magnesium has been shown to be effective on its own, even better results may be achieved by combining it with vitamin B_6 and other nutrients. Several studies have shown that when PMS patients are given a multivitamin/multimineral supplement containing high doses of magnesium and pyridoxine, they experience a substantial reduction in PMS symptoms.[57,58]

The optimal intake of magnesium should be based on body weight, 6 mg/kg. For a 50-kg woman, the recommendation would be 300 mg; for a 90-kg woman, 540 mg. Because these doses are difficult to achieve by diet alone, supplementation is recommended. In the treatment of PMS, a dose of twice this amount, 12 mg/kg, may be needed.

Magnesium bound to aspartate or one of the Krebs cycle intermediates (malate, succinate, fumarate, or citrate) is preferred to magnesium oxide, gluconate, sulfate, or chloride because of better absorption and fewer side effects (laxative effects).[59,60]

Calcium

Calcium has emerged as a common nutrient to supplement for PMS. Because calcium regulation and calcium deficiency can actually mimic some PMS symptoms, supplemental calcium has been tested as a treatment. An important multicenter clinical trial was conducted in 479 women who were given either 1200 mg of calcium carbonate or placebo for three menstrual cycles.[61] A significantly lower symptom score was observed in the calcium group during the luteal phase of the cycle for both the second and third cycles. By the end of the third cycle, calcium resulted in a 48% reduction in total symptom scores from baseline compared with a 30% reduction in the placebo group. Other studies also show improvements in PMS symptomatology with calcium supplementation (1000 to 1336 mg).[62,63] In one of the later studies, calcium and manganese supplementation (1336 and 5.6 mg, respectively) improved mood, concentration, and behavior. In another study, 1000 mg/day improved mood and water retention.[62]

Zinc

Zinc levels have been shown to be low in women with PMS.[64] Zinc is required for proper action of many body hormones, including the sex hormones, as well as in the control of the synthesis and secretion of hormones. In particular, zinc serves as one of the control factors for prolactin secretion.[65] When zinc levels are low, prolactin release increases, and high zinc levels inhibit this release. Hence, in high-prolactin states, zinc supplementation is very useful. An effective dose range for zinc supplementation for elevated prolactin levels in women is 30 to 45 mg in the picolinate form.

Vitamin E

Although vitamin E research concerning PMS has focused primarily on breast tenderness, significant reduction of other PMS symptoms has also been demonstrated in double-blind studies.[16,66] Nervous tension, headache, fatigue, depression, and insomnia were all significantly reduced. In one double-blind

study, patients receiving vitamin E (400 IU/day) demonstrated a 33% reduction in physical symptoms (such as weight gain and breast tenderness), a 38% reduction in anxiety, and a 27% reduction in depression after 3 months of use. In contrast, the placebo group reported only a 14% reduction in physical symptoms. The group taking vitamin E also noted higher energy levels, fewer headaches, and fewer cravings for sweets.

See Chapter 165 for further research on vitamin E and mastalgia.

Essential Fatty Acids

Women with PMS have been shown to exhibit essential fatty acid and prostaglandin abnormalities, the chief abnormality being a decrease in gamma-linolenic acid (GLA).[67] GLA is derived from linoleic acid. This conversion requires adequate levels of vitamin B_6, magnesium, and zinc, because these nutrients function in delta-6-desaturase, the key enzyme responsible for this conversion. Given that a deficiency of one or more of these nutrients is common in PMS, decreased GLA levels could almost be expected.

Evening primrose, black currant, and borage oils contain GLA, typical levels being 9%, 12%, and 22% respectively. Although these essential fatty acid sources are quite popular, the research on GLA supplements in the treatment of PMS shows no benefit over placebo. In the four double-blind crossover controlled trials of evening primrose oil, this issue may be complicated by a very high response in the placebo group.[68,69] One of these studies used 3 g/day and the others used 4 g/day. A meta-analysis of the clinical trials of evening primrose oil concluded that it is of little value in the management of PMS.[68]

Multiple Vitamin and Mineral Supplements

A high-quality multivitamin/multimineral supplement providing all of the known vitamins and minerals can serve as a foundation on which to build. Women with PMS have two very sound reasons for taking a high-potency multiple vitamin:

- Nutritional deficiency is relatively common among women with PMS.
- High-potency multivitamin/multimineral formulations have been shown to have significant benefits in PMS.

The frequency of nutritional supplementation and the calculated intake of select nutrients have been shown to be much lower in patients with PMS than in normal women. Women with PMS have been shown to consume vitamins in their food at levels close to the recommended daily allowance, but compared with women who did not have PMS, their intake levels were only 2.2% as much for thiamin, 2.2% for riboflavin, 16.7% for niacin, 8.7% for pantothenic acid, and 2.7% for pyridoxine.[16]

Several double-blind studies have shown that patients with PMS who were given a multivitamin/multimineral supplement containing high doses of magnesium and pyridoxine experience reductions (typically at least a 70% reduction) in both premenopausal and postmenstrual symptoms.[57,58]

L-Trytophan

As discussed earlier in this chapter, decreases in serotonin may be the cause of PMS or at least may exacerbate PMS. Tryptophan is a precursor to serotonin. Studies using L-tryptophan in daily doses of 6 g/day for 17 days from ovulation to day 3 of menses has led to significant reductions in mood swings, insomnia, carbohydrate cravings, tension, irritability, and dysphoria.[70,71] As 5-hydroxytryptophan (5-HTP) has shown superior results to tryptophan in depression, it may also prove to be a more effective option for raising serotonin levels in PMS. For more information, see Chapter 98.

Botanical Medicines

Many plants have been used throughout traditional botanical medicine for cyclic premenstrual symptoms. These have tended to include what are called reproductive tonics, adaptogens, liver detoxification herbs, and "hormonal balancing" herbs. Unfortunately these botanical approaches have not been the subject of clinical evaluation. Instead, modern research has focused on the following botanicals for relief of PMS symptoms: chaste berry, St. John's wort, and *Ginkgo biloba*.

Vitex agnus castus (chaste tree)

The chaste tree *(V. agnus castus)* is native to the Mediterranean, where its berries have long been used for women's health. Chaste berry extract is probably the single most important herb in the treatment of PMS, not only because of its long tradition and known historical uses but also as a result of modern scientific research. In two surveys of gynecologic practices in Germany, physicians graded chaste berry extract as good or very good in the treatment of PMS. More than 1500 women participated in the studies.[72,73] One third of the women experienced complete resolution of their symptoms, and another 57% reported significant improvement.

The beneficial effects of chaste tree in PMS and these other conditions appear to be related to alterations in gonadotropin-releasing hormone and follicle-stimulating hormone-releasing hormone. In other words, it appears that chaste berry extract has profound effects on the hypothalamus and pituitary function. As a result, it is able to normalize the secretion of other hormones—for instance, reducing the secretion of prolactin and reducing the estrogen: progesterone ratio.

In a more recent study, a randomized clinical trial compared a chaste tree standardized extract (20-mg tablet standardized for casticin) with placebo in women with PMS.[74] One hundred and seventy women with PMS were assigned to take either the chaste tree or a placebo once daily for three consecutive menstrual cycles. Women were asked to rate changes in PMS symptoms, such as irritability, mood changes, anger, headache, breast tenderness, and bloating. At the end of the trial, women taking the chaste tree reported a 52% overall reduction in PMS symptoms, compared with only 24% for those taking placebo. Women taking the chaste tree extract reported significantly greater reductions in irritability, mood changes, anger, headache, and breast tenderness than the women taking the placebo. Bloating was the only symptom that did not change significantly with chaste tree. Another study has looked at the effectiveness of chaste tree extract versus fluoxetine in decreasing PMS symptoms and found the two treatments to have comparable results, with the main difference being that fluoxetine was more effective in treating psychological symptoms and chaste berry was more effective with physical symptoms.[75]

In more recent research, Chinese women suffering from moderate to severe PMS were studied in a prospective double-blind placebo controlled parallel-group multicenter clinical trial.[76] The chaste tree extract contained 4.0 mg of dried ethanolic (70%) extract. The mean total Premenstrual Syndrome Diary (PMSD) score decreased from 29.23 at baseline to 6.41 at the end of the third cycle for the chaste tree group and from 28.14 at baseline to 12.64 at the end of the third cycle for the placebo group. The difference in the PMSD score from baseline to the third cycle was significantly lower in the treatment group than in the placebo group. The Premenstrual Tension Syndrome Self-Rating Scale decreased from 26.17 at baseline to 9.92 for the treatment group and from 27.10 to 14.59 for the placebo group—similar positive results as the PMSD scores.

PMS is also very common in perimenopausal women. A study was undertaken to evaluate the effectiveness of a combination of St. John's wort and chaste berry in the treatment of PMS-like symptoms in perimenopausal women.[77] This clinical trial was conducted over 16 weeks and information rating PMS scores in perimenopausal women who were experiencing irregular menses was collected at 4-week intervals. The daily dose of herbal products given was 3 tablets containing 5400 mg of St. John's wort standardized to contain 990 mcg hypericins, 9 mg hyperforin, and 18 mg flavonoid glycosides. The daily dose of chaste tree was one tablet of an extract equivalent to 1000 mg of dried fruit. Participants recorded the severity of their PMS symptoms using the Abraham's Menstrual Symptom Questionnaire. Results for the active treatment group were statistically superior to placebo for total PMS-like symptoms as well as subgroups of PMS depression and PMS food cravings.

Ginkgo biloba

Several compounds and mechanisms of *Ginkgo* may be involved in physical and psychological benefits for PMS (see Chapter 93). In the first randomized placebo-controlled clinical trial evaluating *G. biloba* extract (GBE) in PMS, 165 women of reproductive age who had fluid retention, breast tenderness, and vascular congestion were assigned to receive either a GBE of 25% *Ginkgo* flavone glycosides at 80 mg twice daily or a placebo from day 16 to day 5 of their cycles. Symptom diaries kept by patients and physician evaluation of symptoms demonstrated that *G. biloba* extract was effective against the congestive symptoms of PMS, particularly breast pain and breast tenderness.[78]

In a subsequent study, GBE was evaluated using Beck's Depression Inventory, a daily symptom rating questionnaire containing 19 PMS symptoms according to DSM-IV, and items relative to the inclusion criteria included participants experiencing the symptoms for at least two consecutive cycles before the study and experienced at least 5 of the 19 symptoms for most of the time during the last week before menses. Eighty-five women completed the study. Participants were given 40 mg three times daily of a standardized GBE or a placebo from day 16 of their cycle to day 5 of their next cycle. Overall severity of symptoms in the GBE group was 34.80% before the treatment, which fell to 11.11% after the treatment. In the placebo group, the baseline severity was 34.38%, which dropped to 25.64% after intervention. The severity of the psychological and physical symptoms also declined significantly in both groups, but there was again a significant difference between the two groups, in favor of the GBE.[79]

Hypericum perforatum

Owing to the influence of St. John's wort on serotonin (see Chapter 99), it should not be surprising that this herb would be an important botanical in the treatment of PMS, and research has affirmed this. A randomized double-blind placebo-controlled crossover trial of 36 women with regular menstrual cycles and mild PMS was done in which women were randomly assigned to receive St. John's wort tablets (900 mg/day and standardized to 0.18% hypericin and 3.38% hyperforin) or placebo for two menstrual cycles.[80] After a 1-month no treatment cycle, women were crossed over to the opposite group for two additional cycles. Symptoms were rated using the Daily Symptom Report, State Anxiety Inventory, Beck Depression Inventory, Aggression Questionnaire, and Barratt Impulsiveness Scale. Numerous hormones and physiologic markers were also measured in the follicular and luteal phases: follicle-stimulating hormone (FSH), luteinizing hormone (LH), estradiol, progesterone, prolactin, testosterone, cytokine, interleukins (IL-1B, IL-6, and IL-8), interferon, and tumor necrosis factor alpha.

St. John's wort was statistically more beneficial than placebo in relieving food cravings, swelling, poor coordination, insomnia, confusion, headaches, crying, and fatigue. There were no significant effects of St. John's wort compared with placebo in any of the biochemical blood measurements. St. John's wort was not statistically more beneficial in anxiety, irritability, depression, nervous tension, mood swing, feeling out of control, and pain-related symptoms during two cycles of treatment. However, these pain-related symptoms appeared to improve more than with placebo toward the end of each treatment period.

In a prospective, open, uncontrolled observational study, 19 women who were diagnosed with PMS completed a daily symptom rating questionnaire for one menstrual cycle and underwent a screening interview with physicians. The participants then took St. John's wort tablets (300 mg St John's wort standardized to 900 mcg of hypericin) for two complete menstrual cycles.[81] Symptoms were rated daily by means of the Hospital Anxiety and Depression scale and modified Social Adjustment Scale, which were administered at baseline and after each of the two cycles. The degree of improvement in overall PMS scores between the beginning of the study and the end was 51%, with more than two thirds of the women having at least a 50% decrease in the severity of symptoms. The mood subscale showed the most improvement (57%); the symptoms with the greatest reductions in scores were crying (92%), depression (85%), confusion (75%), feeling out of control (72%), nervous tension (71%), anxiety (69%), and insomnia (69%).

Saffron (Crocus sativus L.)

Saffron has been previously shown to have an antidepressant effect in women with mild to moderate depression through a serotonergic mechanism, so it is not surprising that it would be beneficial in PMS. A double-blind placebo-controlled trial was done to study whether saffron could be used to relieve PMS symptoms. Fifty women of reproductive age with regular menstrual cycles and PMS symptoms for at least the last 6 months were randomly assigned to receive 15 mg of saffron twice daily or placebo twice daily for four full menstrual cycles.[82] The Daily Symptom Report and the Hamilton Depression Rating Scale were used to evaluate the response. According the Daily Symptom Report, 19 of the 25 women in the saffron group responded with at least a 50% reduction in severity of symptoms versus only 2 of 25 in the placebo group (P <0.0001). A significant difference between the saffron and placebo groups occurred between the third and fourth cycles and was statistically significant by the end of the study (P <0.0001). According to the Hamilton Depression Rating Scale, 15 of 25 women in the saffron group responded to treatment versus only 1 of 25 in the placebo group. (P <0.0001). Again, a significant difference was seen between the third and fourth cycles, with a statistically significant difference by the end of the study (P <0.0001).

Bioidentical Progesterone Therapy

Bioidentical progesterone, also called natural progesterone, is a white crystalline powder most often made by extracting diosgenin from Mexican wild yam and then converting this in a manufacturing laboratory into a progesterone molecule that is biochemically identical to the body's own progesterone. It is not wild yam, nor should it be considered an herbal product. What makes natural progesterone "natural" is not so much that it is made from plant material but rather that it is identical to the progesterone hormone produce in a woman's ovaries. Conventional medical practitioners have historically used a synthetic version, called progestin, which is found in birth control pills as a hormonal treatment for PMS. This

has largely been replaced by using select antidepressants for their effect on serotonin levels. Although bioidentical progesterone has been studied in controlled clinical trials for the treatment of PMS, efforts to consistently demonstrate the superiority of progesterone therapy over placebo have failed (possibly because there is a significant placebo response in PMS).[83-88] The studies showing positive effects have used dosages of 200 to 400 mg twice daily as a vaginal or rectal suppository from 14 days before the expected onset of menstruation until the onset of vaginal bleeding.[87,88] Transdermal creams of natural progesterone generally sold in natural foods/nutrition stores have been a popular self-treatment for PMS. These products vary greatly from an herbal wild yam cream only to wild yam cream with bioidentical progesterone added, up to 20 mg per ¼ tsp. Side effects are few and tend to be generally mild, but they may occur in 4% to 5% of individuals using transdermal creams that include 20 mg of USP progesterone per one quarter teaspoon. In one of the later double-blind studies that did show a positive effect for progesterone therapy (400 mg twice a day by vaginal or rectal administration), adverse events were reported by 51% of patients in the progesterone group compared with 43% in the placebo group.[88] Irregularity of menstruation, vaginal itching, and headache were reported more frequently by the women taking the progesterone.

THERAPEUTIC APPROACH

The approach to the woman with premenstrual symptoms first involves an evaluation of symptoms and the establishment of a diagnosis. In an effort to clarify the treatment approach, the clinician should consider the following seven key steps:

1. Evaluate PMS symptoms by having the patient complete a questionnaire.
2. Rule out psychiatric or other medical conditions.
3. Have the patient adopt the following dietary recommendations for PMS:
 - A vegetarian, low-fat, low-sugar, low-salt, high-fiber diet is advised; if there is mastalgia, caffeine should be avoided.
4. The patient may also benefit from the guidelines for nutritional supplementation given below.
5. Select the appropriate herbal support.
6. Establish a program for stress reduction and recommend regular exercise.
7. If, after at least three complete periods, the patient is not experiencing a significant improvement or complete resolution of symptoms, additional causative factors should be sought, as detailed above, or change made to the treatment program.

Nutritional Supplements

- High potency multivitamin/multimineral formula
- Vitamin B_6: 50 to 100 mg/day (total days dose of vitamin B_6 in a single ingredient or in the multiple vitamin should not exceed 150 mg)
- Magnesium (preferably citrate, malate, aspartate,or glycinate): 250 mg twice a day
- Zinc: 15 to 20 mg/day
- Vitamin E: 200 to 400 IU/day

Botanical Medicines

Vitex agnus castus:
- Standardized extract (0.5% agnuside): 175 to 225 mg a day or 20 mg standardized to casticin
- Liquid extract: 2 mL/day

Ginkgo biloba:
- 80 to 160 mg standardized extract (24% ginkgoflavonglycosides) twice a day

Hypericum perforatum:
- 900 to 1800 mg standardized extract (0.3% hypericin content) a day

ANORECTAL ANATOMY

The anorectal region is divided into the anus, which extends anywhere from 3 to 4 cm above the anal verge to its merge with the rectum, and the rectum, which is 12 to 18 cm long. The anal verge is the demarcation point from perianal skin to anal skin. The anal canal can further be divided into the dentate and anorectal lines. The dentate line is the demarcation point between the ectoderm of the external squamous epithelium and the rectal entodermal mucosa. The anal canal does not contain sebaceous or sweat glands and is innervated by somatic nerves up to and slightly beyond the dentate line, which make it sensitive to pain to varying degrees. Above the dentate line the rectal mucosa is relatively insensitive to pain but registers distention and inflammation as diffuse visceral pain. The anorectal line is the point above which the rectum expands outward into the pelvic bowl.

The area between the dentate and anorectal lines contains the rectal columns, anal valves, anal glands, and anal crypts. The anal glands normally provide mucus for lubrication with passage of stool and empty into the anal crypts. This area becomes the source of an anal fistula or perirectal abscess if the crypt becomes impacted and cannot discharge its mucus. Anal fissures lie below the dentate line. Midway between the dentate and anorectal lines lies the white line of Hilton, or pectinate line. This is the location of the intersphincteric groove, the region that lies between the internal and external sphincters. The internal sphincter is under control of the autonomic nervous system, and the external sphincter is under somatic or voluntary control.

The anorectal region is highly vascularized and receives its blood supply from both the inferior mesenteric artery and the internal iliac artery. Arterial flow is then diverted from these sources through the superior, middle, and inferior rectal arteries. There is considerable anastomosis among these branches. Venous return is facilitated by the superior and middle hemorrhoidal veins, which empty into the inferior mesenteric veins and subsequently the portal vein, and the internal iliac vein, which subsequently empties into the vena cava, bypassing the liver.

The levator ani muscle forms the floor of the pelvis and helps form the puborectalis sling. The pull of the puborectalis sling causes the bowel to change direction as it penetrates the pelvic floor, making passage of stool easier. Along with the internal and external rectal sphincters, these muscles form the sphincter mechanism that controls continence. The anal canal receives its innervation via the pudendal nerves originating from S2, S3, and S4.[1,2]

A wide variety of presenting symptoms are related to disorders of the anorectum. Among them are pain, tenderness, rectal spasm, bleeding, itching, protrusions, eruptions, discharges, constipation, diarrhea, changes in stool pattern, sacral backache, shooting pains down the limbs, crampy and painful menses, urinary disturbances, anemia, prostatitis, restlessness in children, and foreign bodies.[3] The clinician should be aware that seemingly unrelated symptoms might, in fact, have their origin in the anorectal tract.

ANAL DISEASES

Anal Fistula and Anal Abscess

Anal fistula and anal abscess result from an infection of an anal crypt, whose distal end lies near the dentate line. The anal glands, which lie within the intersphincteric

groove and empty into the anal crypts, become infected because of impacted feces. The resulting infection makes its way into the intersphincteric space but generally does not penetrate beyond the external sphincter. Most of the anal glands lie posteriorly; therefore, most abscesses drain from a line posterior to the ischial tuberosities, whereas anterior abscesses drain radially from their points of origin. The presence of a rectal fistula or abscess may point to an internal bowel disease such as diverticulitis, trauma to the area, or immune system incompetence, as with the human immunodeficiency virus (HIV).

Under normal conditions the highly vascularized rectal mucosa is able to provide adequate protection against the spread of infection. The weak points are the anal glands, however, because they may become impacted with fecal matter, setting up an infective process in the anal crypt and intersphincteric space. The surrounding perianal tissue is swollen, red, and painful to palpation. If the infection remains in the intersphincteric space, the patient has rectal pain seemingly without specific findings. Eliciting the pain with pressure upon examination may provide a clue to the source of the lesion. The patient may also present with a fever of unknown origin.

The adjacent ischiorectal fossae are regions filled with fatty tissue that allow for distention of the rectum. Therefore, an abscess has many different directions in which to track, setting up areas for pockets of pus. In a true perianal abscess, incision and drainage are usually not recommended because the bulk of the lesion would remain untouched owing to the probable invasion of the underlying tissues and the propensity of such an access to form caverns of pus. Unlike other abscesses formed by the body, perianal abscesses should not be allowed to come to a head and rupture on their own; such an occurrence can lead to excessive inflammatory necrosis of the anal sphincter.

Generally a surgical consultation is warranted for a rectal abscess. Surgery allows for opening of the tract and healing by second intention. However, localized treatment can be undertaken to help the abscess drain if it has ruptured on its own or the patient presents acutely and immediate referral is not possible. Such treatment affords some relief and helps decrease the morbidity associated with this condition. Irrigation with herbal antibacterial agents such as *Hydrastis*, *Usnea*, and *Calendula succus* in 0.9% saline helps drainage.

Another, often encountered scenario is that of folliculitis with resultant abscess formation. These abscesses can be incised and drained, because they do not involve the anal canal or ischiorectal fossa. Homeopathic medicines such as calcarea sulphuricum, silicea, hepar sulphuris, and *Myristica* are some of the more often indicated medicines. Poultices made of onion, garlic, or potatoes exert a drawing action, bringing the lesion to a head faster. Alternating hot and cold sitz bath is also useful. Once the abscess has broken open or has been incised and drained, irrigation with the previously mentioned solution hastens healing.

Anal Cryptitis

Anal crypts are pockets created between the grooves formed by the rectal columns at their distal points ending at the dentate line. Anal glands empty into the crypts and, as previously mentioned, are believed to be the source of anal fistula. That anal cryptitis is a separate entity is open to some debate, and it is rarely seen. The patient complains of pain that is worse with bowel movement. Examination shows localized tenderness and redness at the dentate line, and there may be some rectal spasm. Rectal fissure should be ruled out. Chronic cases suggest bacterial infection, usually gonorrhea.

Treatment is by herbal suppository, sitz baths, increasing dietary fiber intake, and, if necessary, localized anesthesia. The crypt may be cleaned out with a crypt hook if needed and irrigated with a solution of *Calendula succus* and *Hydrastis* in normal saline.

Anal Fissure

An anal fissure is a slit-like separation of the anal mucosa lying below the dentate line. The majority of fissures are found in the posterior midline region (70% to 80%), but anterior midline lesions (10% to 20%) are more commonly seen in women. Some investigators report that fissures are more common in men than women,[4] but other studies do not bear this out.[5] In some patients the anal sphincter is more oval than round, coming to a Y or narrow point at the posterior midline, making for a greater predisposition for anal fissure. Anal fissure in children is not all that uncommon, often being associated with chronic diarrhea or hard stool.[6] Fissure may also be a complication of a lesion associated with a congenital anal deformity. Lesions located in the anteroposterior vertical axis suggest an internal bowel disease, such as Crohn's disease, squamous cell carcinoma or adenocarcinoma of the rectum, syphilitic fissure, or ulceration due to tuberculosis.

Anal fissures are very painful because of their somatic innervation, which results from spasm of the anal sphincter in response to stretching during the passage of stool. The presence of an anal fissure triggers a vicious cycle of pain, causing sphincter spasm, which contributes to a tightening of the sphincter and increased pain with passage of stool. Patients usually have severe pain during and for some time after defecation, and bleeding is not uncommon. As the lesion enlarges it may ulcerate and become infected. Conventional medical treatment consists of rectal dilation, internal sphincterotomy, electrodessication, or surgical excision.[5]

Anal fissure can be caused by passage of large hard stools, childbirth trauma, chronic diarrhea, trauma, food allergy, or prolonged straining to pass stool. Infants and young children who consume large amounts of cow's milk are more likely to have anal fissures and chronic constipation, especially if they were breast fed for a shorter period.[7] Many of the patients in whom anal fissures develop display intense, compulsive personalities that may contribute to the formation of such fissures as well as the ability to heal. A previous anal or rectal operation, syphilis, or Crohn's disease also predisposes the patient to fissure development.

Examination may be difficult because of the pain and spasm, and anoscopic examination is often out of the question unless anesthesia is used. A localized injection of 1% or 2% lidocaine into the rectal sphincter at the 3-o'clock and 9-o'clock positions can help relax it enough for an examination to occur. One can often see anal fissures without using an anoscope simply by pulling back on the anal skin and examining the tissue. Presence of a sentinel pile or enlarged papilla suggests chronic anal fissure and is the result of inflammation and the body's attempt to protect the inflamed area. Anal spasm may be marked, making it difficult to perform an examination, and anal stenosis and fibrosis may be present if the condition has been chronic.

Clinicians should consider the presence of Crohn's disease, especially if the patient is younger, there is a history of periodic or chronic diarrhea, and the fissure lies in the anteroposterior vertical axis. Squamous cell carcinoma, syphilitic ulcers, and rarely tuberculosis should be considered as part of the differential diagnosis. Spasm of the levator ani muscle may also make one think of anal fissure, but no lesion is present in this case.

Treatment of anal fissure can prove to be one of the more difficult courses of therapy for both the patient and the clinician.

Although surgical intervention removes the lesion and alleviates the pain, the lesion invariably returns because the underlying cause has not been addressed. Additionally, surgical intervention often predisposes to fecal incontinence later in life. Therefore, medical management both in the short and long terms is necessary for complete resolution. Patients must be cautioned that the healing of a rectal fissure has its periods of exacerbation and remission and that continuing with the treatment protocol is important despite the periodic setbacks that are often encountered. Educating the patient on this point upon initiation of therapy is essential to its success.

Treatment

Initial treatment should be to alleviate the pain and spasm, because often they have brought the patient to the office. Homeopathic medicines provide prompt relief if the simillimum is found and aids the healing process. Remedies such as *Chamomilla*, graphites, nitric acid, *Ratanhia*, *Sepia*, silicea, and *Thuja* are some of the more often indicated medicines, but others may also be needed.[8,9] Frequent dosing is generally the rule. Protease 315 mg, two capsules three times daily between meals and again before bed, will help to alleviate pain as well. A preparation of 0.2% glycerol trinitrite can be used topically to relieve rectal spasm,[10] as can 5% lidocaine cream for localized pain. Glycerol trinitrite has been shown in a number of studies to be effective in relieving rectal spasm as well as increasing blood flow to the anal sphincter.[11-13] Reduced blood flow to the anal sphincter has been postulated as one of the precipitating mechanisms for the development of an anal fissure.

A topical cream consisting of vitamins A and E, panthenol, *Calendula*, and *Comfrey* will considerably enhance the healing process by providing nutrients essential for healing by second intention. Some of the commercial preparations also contain boric acid, which acts as a styptic. Initially, the cream should be applied topically after every bowel movement and at bedtime. As healing occurs, twice-daily application usually suffices until the lesion has resolved.

Iontophoresis using a zinc electrode and applying a positive current helps facilitate healing by hardening the underlying fissure, decreasing bleeding, and affording pain relief.[14] The patient lies on the negative dispersing pad and current is applied for 10 minutes at 10 mA.

The patient should be instructed not to strain during passage of stool and to use cotton balls that have been moistened with water rather than toilet paper or chemical or alcohol wipes. Some patients are excessive cleaners; they should be instructed that it is unnecessary to wipe deep into the anal canal because doing so makes the condition worse.

Sitz baths also aid in the healing process by providing increased blood flow to the area. If performing a sitz bath is not possible, alternately spraying hot and cold water on the perineal area will achieve the same result.[15]

Increasing dietary fiber is necessary if the condition is due to chronic constipation, whereas chronic diarrhea can be managed through a variety of therapeutic approaches once the cause is found. Dietary changes are a must, especially if the anal fissure is associated with irritable bowel syndrome or Crohn's disease. The higher rates of hemorrhoids and Crohn's disease seen in blood group O individuals are believed to be due to food intolerance.[16]

As previously mentioned, the clinical course varies from patient to patient and seems to depend partially on whether the patient follows the treatment plan religiously. Frequent follow-up is needed to assess the healing process and reassure the patient. Once healing has occurred, proper bowel function and good dietary and bowel habits must be maintained in order to prevent further episodes. Patients who experience an anal fissure are at risk for further episodes.

HEMORRHOIDS

Affliction from hemorrhoids has been noted in the writings of various cultures throughout history—Babylonian, Hindu, Greek, Egyptian, and Hebrew. In the United States as well as other industrialized countries, hemorrhoidal disease is extremely common. Although most individuals may begin to have hemorrhoids in their twenties, hemorrhoidal symptoms usually do not become evident until the fourth decade of life.[17,18] Estimates have indicated that 50% of persons older than 50 years have symptomatic hemorrhoidal disease at one time or another and up to one third of the total U.S. population has hemorrhoids to some degree.[19]

The causes of hemorrhoidal disease are similar to those of varicose veins. As with varicose veins, predisposition to the development of hemorrhoids depends on genetic makeup. Excessive venous pressure, pregnancy, long periods of standing or sitting, straining at stool, and heavy lifting are considered the major factors. Most patients have more than one predisposing factor.[20]

Because the portal venous system contains no valves, factors that increase venous congestion in the perianal region can precipitate hemorrhoid formation. They include increasing intra-abdominal pressure (e.g., defecation, pregnancy, coughing, sneezing, vomiting, physical exertion, and portal hypertension due to cirrhosis), increase in straining during defecation, and standing or sitting for prolonged periods.

Presenting symptoms are itching, burning, irritation with passage of stool, swelling of the anus and perianal region, blood on the toilet paper or in the bowl, and seepage of mucus. Most patients attribute all rectal symptoms to hemorrhoids; however, internal hemorrhoids are only rarely painful or cause itching. Usually the hallmark of a hemorrhoidal eruption is bleeding or protrusion noted after passage of stool. Pain from internal hemorrhoids occurs when they become strangulated from prolapse and with thrombosis. Any other pain associated with hemorrhoids is usually due to a coexisting lesion such as a fissure. Itching is rarely associated with internal hemorrhoids except if there is excess mucus discharge.

Classification

Hemorrhoids are typically classified according to location and degree of severity. External hemorrhoids occur below the anorectal line. They may be full of either blood clots (thrombotic hemorrhoids) or connective tissue (cutaneous hemorrhoids). A thrombotic hemorrhoid is produced when a hemorrhoidal vessel has ruptured and formed thrombus, whereas a cutaneous hemorrhoid consists of fibrous connective tissue covered by anal skin. Cutaneous hemorrhoids can be located at any point on the circumference of the anus. Typically, they are caused by the resolution of a thrombotic hemorrhoid; that is, the thrombus becomes organized and replaced by connective tissue.

Internal hemorrhoids occur above the anorectal line. Occasionally an internal hemorrhoid enlarges to such a degree that it prolapses and descends below the anal sphincter. Internal hemorrhoids are graded by the degree of prolapse.

Grade I: No prolapse

Grade II: Prolapse upon defecation but spontaneous reduction

Grade III: Prolapse upon defecation and manual reduction
Grade IV: Prolapsed and no reduction possible

Internal-external, or mixed, hemorrhoids are a combination of contiguous external and internal hemorrhoids that appear as baggy swellings. The following types of mixed hemorrhoids can occur:

- Without prolapse: bleeding may be present, but there is no pain.
- Prolapsed: characterized by pain and possibly bleeding.
- Strangulated: the hemorrhoid has prolapsed to such a degree and for so long that its blood supply is occluded by the anal sphincter's constricting action; strangulated hemorrhoids are very painful and usually become thrombosed.

Treatment

In contrast to the United States and the United Kingdom, hemorrhoids are rarely seen in parts of the world where high-fiber diets containing unrefined foods are consumed.[19] A low-fiber diet high in refined foods contributes greatly to the development of hemorrhoids. Individuals consuming a low-fiber diet tend to strain more during bowel movements, because their smaller and harder stools are more difficult to pass. This straining raises the pressure in the abdomen, obstructing venous return. The greater pressure will increase pelvic congestion and may significantly weaken the veins, causing hemorrhoids to form.

A high-fiber diet is perhaps the most important component in the prevention of hemorrhoids. A diet rich in vegetables, fruits, legumes, and grains promotes peristalsis because many fiber components attract water and form a gelatinous mass that keeps the feces soft, bulky, and easy to pass. A high-fiber diet leads to significantly less straining during defecation.

Natural bulking compounds can be used to reduce fecal straining. These fibrous substances, particularly psyllium seeds and guar gum, possess a mild laxative action owing to their ability to attract water and form a gelatinous mass. They are generally less irritating than wheat bran and other cellulose fiber products. Several double-blind clinical trials have demonstrated that supplementing the diet with bulk-forming fibers can significantly reduce the symptoms of hemorrhoids (bleeding, pain, pruritus, and prolapse) and improve bowel habits.[21,22] The use of psyllium seed fiber has been shown to afford significant relief in bleeding and pain within 6 weeks in hemorrhoid suffers.[23]

A placebo-controlled randomized study evaluated the efficacy of fiber supplements in 50 patients with bleeding internal hemorrhoids. Patients in the study group were treated with a commercially available preparation of *Plantago ovata* and those in the control group were treated with a placebo. Endoscopy was performed in every patient before and after treatment to establish the degree of hemorrhoidal prolapse as well as the numbers of congested hemorrhoidal cushions and contact-bleeding hemorrhoids. During the first 15 days of treatment, the average number of bleeding episodes was 4.8 ± 3.8 for the study group versus 6.4 ± 3 for the control group (NS). During the following 15 days, it decreased to 3.1 ± 2.7 in the study group versus 5.5 ± 3.2 (P <0.05) in the control group, and in the last 10 days of treatment a further reduction to 1.1 ± 1.4 was found in the study group compared with 5.5 ± 2.9 in the control group (P <0.001). The number of congested hemorrhoidal cushions diminished from 2.6 ± 1 to 1.6 ± 2.2 after fiber treatment (P <0.01) but no differences were found in the control group. In the fiber group, hemorrhoids bled on contact in 5 out 22 patients before treatment and in none after treatment; no differences were found in the control group. No modification of the extent of prolapse was observed after treatment.[24] Although the effect took a few weeks to develop, the final results were very impressive.

Another important, but only recently recognized dietary factor is breakfast. An age-, gender-, and pregnancy-matched case-control study carried out in an outpatient clinic found a remarkable 7.5-fold increase in the odds of suffering from hemorrhoids or anal fissures in matched subjects who did not eat breakfast![25]

Flavonoid preparations have been shown to be beneficial in the prevention and treatment of hemorrhoids through their strengthening effect on venous tissues. Although early studies primarily used rutin, later research has used hydroxyethylrutosides (HERs).

Several of the studies have been performed in pregnant women, where HERs were shown to be of great benefit in helping to relieve hemorrhoidal signs and symptoms. In one study, 90% of the women given HERs (1000 mg daily for 4 weeks) experienced improvement of symptoms, compared with only 12% in the placebo group.[26] Similar results in hemorrhoids not associated with pregnancy have been reported.[27,28] Another study provided a micronized flavonoid combination (diosmin 90% and hesperidin 10%) for a median of 8 weeks before delivery and 4 weeks after delivery to 50 pregnant women with acute hemorrhoids. Their therapy was very successful, with 66% of patients reporting relief from symptoms by the fourth day of treatment and fewer suffering relapses during the antenatal period.[29] Treatment was well accepted and did not affect pregnancy, fetal development, birth weight, infant growth, or feeding.

In most circumstances, topical treatments for acute or chronic hemorrhoids involving the use of suppositories, ointments, and anorectal pads provide only temporary relief. Many over-the-counter products for hemorrhoids primarily contain natural ingredients, such as witch hazel *(Hamamelis)*, cocoa butter, Peruvian balsam, zinc oxide, allantoin, and homeopathic preparations. Many patients use hydrocortisone cream to help with the itching that they associate with hemorrhoids; prolonged use of this agent can often aggravate the pruritus ani, setting up a cycle of continued use.

Botanical Medicines

Botanical medicines have had a long history of use for hemorrhoids. They can be used topically, as suppositories, or taken orally to support redundant tissue and facilitate healing. Use of rectal suppositories after galvanic, infrared, or laser therapy helps facilitate healing and decrease bleeding. Some of the more commonly used botanical medicines are discussed later in this chapter.

Hydrotherapy

The warm sitz bath is an effective noninvasive treatment for uncomplicated hemorrhoids.[15,18] Although a warm sitz bath is a useful treatment for an acute hemorrhoidal flare-up, alternating hot and cold sitz baths is better suited to facilitate the healing of chronic conditions.

Surgical Treatment

A variety of surgical and nonsurgical methods of treating hemorrhoids exist, the choice of which often depends on the stage of the hemorrhoid and the expertise of the physician. Stage I or II hemorrhoids can often be managed medically, especially if they are acute. Herbal rectal suppositories along with the indicated homeopathic medicine often aid quick resolution of the flare-up. In uncomplicated cases of stage I or II hemorrhoids, unless the patient is exhibiting symptoms, treatment is usually not

recommended except for increasing dietary fiber and addressing the patient's dietary choices.

Injection of sclerosing agents is useful in stage I and stage II hemorrhoids, but such treatment is contraindicated in patients with anal fissure, inflammatory bowel disease, Crohn's disease, leukemia, or portal hypertension. Sclerosing therapy is not usually effective against stages III and IV hemorrhoids.

Rubber-band ligation of hemorrhoids is a widely used in-office procedure that removes redundant tissue and causes scarring, which is replaced then by new tissue. Following such treatment, patients often have a sense of fullness or pressure in the rectum, and pain occurs if the band is placed too close to the pectinate line. Postbanding bleeding can occur, and there have been reports of complications resulting in septicemia and death.[20] Rubber-band ligation is used primarily for stage I, stage II, and occasionally stage III hemorrhoids; its success is largely a function of the physician's ability to place the bands.

Cryosurgery involves the application of liquid nitrogen or nitrous oxide to the hemorrhoid, which causes destruction of the venous plexus, scarring, and eventual tissue replacement. Used primarily for stage II and stage III hemorrhoids, the procedure is also useful if condyloma is present. It is contraindicated for stage IV hemorrhoids, chronic ulcers, and acutely thrombosed hemorrhoids. Pain, swelling, and bleeding may occur after cryosurgery.

Hemorrhoidectomy, or the surgical removal of redundant tissue, is by far the most invasive of the hemorrhoidal procedures. It often requires an outpatient surgical setting and causes the patient to lose time from activities of daily living so that healing can take place. Most patients seek alternative treatments in order to avoid surgery and its complications, such as pain and instability of the rectal sphincter.

The monopolar direct current technique for the management of hemorrhoids is becoming a significant treatment of choice in the United States.[30] According to a report by Machicado et al,[31] this painless outpatient treatment of all grades of hemorrhoids is effective and safe. This methodology warrants consideration as the treatment of choice for hemorrhoidal disease.

The first published work on monopolar direct current (also called inverse galvanism) was published by Keesey[32] of Chicago. Dr. Keesey dated the first use of this approach to 1897, although the technical problems (producing a smooth uninterrupted galvanic current source) were not worked out until approximately 1925. The technique then came into use in general practice. Monopolar ablution of hemorrhoidal tissue lost favor in conventional medicine not because it was ineffective but because newer techniques and advances in surgery made it less attractive. If the naturopathic medical schools had not been teaching the Keesey treatment over the last 60 years, it is very possible that this irreplaceable technique would have been lost to the healing arts.

A later study showed that direct-current electrotherapy also relieves the chronic anal fissures often associated with internal hemorrhoids. All 10 of the patients in the reported study experienced relief of chronic anal pain within two treatments, and anal fissures healed in 9 within 4 weeks. One patient experienced a perianal abscess and fistula, requiring surgery. There were no recurrences in 20 months (mean) of follow-up.[31]

The monopolar direct current technique is purely an office procedure. No anesthesia is needed except a local anesthetic for the occasional hypersensitive or nervous patient (in such instances, a 2% procaine solution is injected directly into the hemorrhoid). To date, there have been no reported cases of stricture or metastatic abscesses, a fact that speaks well for the procedure's safety.

The chemicophysiologic action, which causes the absorption and destruction of a vein, is responsible for the permanence of the cure. The mechanism of action of monopolar direct current is well understood. When introduced into the interior of the hemorrhoid, the negative pole of the galvanic current makes contact with the water of the blood and tissues and generates hydrogen gas and hydroxide ions. The hydroxide destroys the organized structure of the hemorrhoid and its capillary circulation. This produces first a hydrolysis and then a hardening of the hemorrhoid. The final disappearance of the hemorrhoid is brought about in one of two ways. It is either absorbed like any bodily contusion or, if the hemorrhoid is large, it ruptures, causing a discharge of the thrombosed elements into the rectum, followed by a contraction of the residual hemorrhoidal tissues.

What makes the Keesey technique attractive is that the patient may be freely ambulant after completion of the procedure and can return to his or her normal activities. The hemorrhoid disappears 7 to 10 days after the treatment. Each separate hemorrhoid is treated in the same manner, and larger hemorrhoids may have to be treated more than once. Generally it is a good policy to treat only one hemorrhoid or at most two at a time because of the healing that must occur and the higher risk of bleeding with the treatment of several.

Infrared coagulation (IRC) is effective with stage I and stage II hemorrhoids but can be combined with the Keesey treatment for stage III and stage IV lesions. Whereas the Keesey technique uses current, the infrared coagulator utilizes a burst of intense heat generated internally and shot through a blue anodized sapphire tip to the surface of the hemorrhoid. The IRC "coagulates" the redundant tissue to a depth that is a function of the duration of the light burst, usually 1 to 1.5 seconds. As with the Keesey technique, a 7- to 10-day period of healing should occur between treatments. Many naturopathic physicians who use the Keesey treatment also incorporate IRC, as doing so usually reduces the number of treatments needed per hemorrhoid. Compared with rubber-band ligation, laser therapy, and cryotherapy, IRC has been shown to produce better results and less morbidity.[33-35]

Prevention

As with all diseases, the primary treatment of hemorrhoids is prevention. This involves reducing factors that may be responsible for increasing pelvic congestion, such as straining during defecation, sitting or standing for prolonged periods, and underlying liver disease. A high-fiber diet is crucial for the maintenance of proper bowel activity, and nutrients and botanical substances that enhance the integrity of venous structures may also be of benefit.

Warm sitz baths and topical preparations are useful to ameliorate the discomfort but have only transient results. A diet high in complex carbohydrates that are rich in dietary fiber is indicated. The diet should contain liberal amounts of proanthocyanidin- and anthocyanidin-rich foods, such as blackberries, cherries, and blueberries, to strengthen vein structures. Supplements such as vitamins A and B complex, antioxidants such as vitamins C and E, and zinc will help maintain vascular integrity and facilitate healing.

When indicated, the monopolar direct current method, specifically designed for the treatment of hemorrhoids, will give permanent results. This technique is especially useful in advanced hemorrhoidal disease and, when coupled with the necessary diet and lifestyle changes, considerably decreases the likelihood of recurrence.

EXTERNAL HEMORRHOIDS

External hemorrhoids occur when there is dilation of the external rectal plexus or thrombosis after an episode of constipation, diarrhea, heavy lifting, or Valsalva effect from sneezing, coughing, or childbirth. The patient notices an often painful perianal lump, and some bleeding may be associated with it. External hemorrhoids usually pose mild to little discomfort and largely resolve on their own if homeostasis is restored. External anal skin tags found on examination are the remnants of previous external hemorrhoids.

If, however, the hemorrhoid becomes thrombosed, a cycle of acute edema and pain is set up that may lead to surgical intervention. As the lesion becomes increasingly distended, varying degrees of pain and swelling can arise, which are often exacerbated by passage of stool or from prolonged sitting. The patient may report bleeding after stool, which is due to a disruption of the hemorrhoid.[36]

A prolapsed internal hemorrhoid should also be considered as part of the differential diagnosis for external hemorrhoid, as should perianal abscess, rectal fissure with sentinel pile, hypertrophied anal papillae, irritated skin tag, condyloma latum, and condyloma acuminata.

Treatment

Unless the hemorrhoid has thrombosed and the patient is in excessive pain, an external hemorrhoid can usually be managed medically. Initial treatment should be to relieve the pressure and dissolve whatever thrombosis has formed. As healing occurs, long-term management in the form of patient education, dietary changes, and enhancement of vascular integrity should be undertaken to help prevent further episodes.

Initial treatment with the enzyme protease 315 mg, two capsules between meals three times daily and two at bedtime, will help reduce the thrombosis and decrease pain. Alternating hot and cold sitz baths act to relieve pain and increase blood flow. A number of homeopathic medicines, such as *Aesculus*, aloe, *Hamamelis*, muriatic acid, *Ratanhia*, and *Sepia*[8,37] are effective in relieving pain and speeding the course of healing. A clinical repertory or materia medica should be consulted, because there are numerous remedies that will provide relief.

Long-term management should involve identification and removal of the precipitating cause and education of the patient as to the cause and how to prevent further episodes. Dietary changes to eliminate offending foods while increasing dietary fiber in the forms of fruits and vegetables or an over-the-counter fiber supplement are warranted. Herbal medicines such as *Aesculus*, *Collinsonia, Hamamelis,* and *Althea* or *Ulmus*[38] will help restore venous sufficiency and soothe inflamed tissues.

In some cases regulation of bowel function with the use of herbal laxatives may be necessary while normal intestinal and colon function is restored. A variety of commercially available herbal medicines and fiber compounds are effective.

In patients who are experiencing an acute episode of a thrombosed external hemorrhoid, prompt surgical excision or incision is in order. Because the external skin is innervated by somatic nerves, administration of anesthesia is needed before evacuation of the clot. Excision leaves a wound that should not be sutured but should be allowed to heal by secondary intention, although this causes greater postoperative pain. Incision and debridement of the clot allow for less pain, but the wound may close too early, leading to re-formation of the thrombus. A text on minor surgery for diseases of the rectum and colon should be consulted as to the proper surgical technique.

Starting the patient on herbal anodynes such as *Piscidia*, belladonna if pain is due to rectal spasm, and *Hyoscyamus niger* can facilitate postoperative management. Healing and pain relief can be afforded with the topical use of *Arnica*, *Hypericum*, and in particular *Calendula succus*.

Alternating hot and cold sitz baths with ½ oz of povidone-iodine added enhances healing and helps reduce the chance of infection. As with medical treatment, protease 2400 milk clotting units (MCUs) can be added for pain relief. Homeopathic agents such as *Arnica*, *Calendula*, and staphysagria should also be considered for pain relief.

PERIANAL DERMATOLOGIC DISORDERS

Condylomata Acuminata

A patient presenting with condylomata acuminata may complain of a sticking or foreign-body sensation perianally. If the lesion is large enough, defecation can be interfered with and hygiene can become a problem. The lesion is usually soft, moist, reddish pink, and pedunculated. Differentiation from condylomata lata of secondary syphilis is necessary because the treaments differ and the potential for transmission is greater with the latter disorder. A rapid plasma reagin (RPR) test with reflexive fluorescent treponemal antibodies (FTA) is warranted. If dark-field microscopic examination is available, it should also be performed. Diagnosis of condylomata acuminata is made through biopsy.

A solution of 25% podophyllum that is applied topically for 6 to 8 hours, after which it is washed off by the patient, has been shown to be effective. Several applications may be necessary in order to eradicate the lesion.[39] Cryosurgery is also available, as is IRC after subcutaneous injection of 1% or 2% lidocaine.[40]Although naturopathic and homeopathic philosophy decries the "suppression" of lesions as contributing to a deepening of the disease process, concomitant administration of the proper homeopathic medicine coupled with a good nutritional program rarely causes this to happen.

Often administration of homeopathic *Thuja* is indicated, but a number of other homeopathic remedies cover genital warts. The taking of a constitutional case not only helps with the eradication of the lesion but also acts to decrease the patient's susceptibility to development of further lesions, which can often happen.

Condyloma Lata

Condyloma lata, or anogenital wart, is caused by human papillomavirus (HPV) types 6, 11, 16, 18, 31, 33, and 35 and is transmitted by sexual contact. Lesions appear as soft, moist, pink to gray flat to pedunculated excrescences frequently found in clusters. More often located in warm, moist regions of the anogenital region, they are more commonly found clustered around the anus in homosexual men and in women who practice anal intercourse.[41]

Lesions must be differentiated from the flat lesion seen with the condyloma lata of secondary syphilis. A diagnosis of squamous cell carcinoma should be considered if the lesion does not respond to therapy, or biopsy can be performed.[42]

Various naturopathic therapies are available, among them being treatment with 25% podophyllum, *Thuja* ointment, homeopathic prescription, cryotherapy, IRC, and electrosurgical dessication.[43]

Lymphogranuloma Venereum

The infective agent in lymphogranuloma venereum (LGV) is one of the serotypes of *Chlamydia trachomatis*, and the lesion may first appear as a papule that ulcerates and heals rapidly. If the primary lesion is in the rectal mucosa, the patient presents with the signs and symptoms of proctitis. This is then followed by the development of inguinal adenitis or buboes that are extremely painful. The later stages may manifest as fistulization, ulceration, fibrosis, and rectal or anal stenosis and can lead to lymphedema of the legs and genitalia. Non-LGV *Chlamydia* serotypes can also be implicated in proctitis but generally do not have as severe presenting symptoms.

White blood cell counts may reach 20,000/mm^3 if there is lymphatic involvement, and the patient may exhibit anemia. Culture of the chlamydial serotype from an infected lesion is diagnostic, but complement fixation and immunofluorescent antibody tests are available.[44]

If LGV is treated promptly, the prognosis is good; but once the disease has begun to affect cellular changes, the prognosis becomes worse as the degree of pathology can be considerable. For the most part allopathic treatment consists of antibiotics such as doxycycline, erythromycin, and sulfisoxazole, all of which have been found to be effective against LGV.[44] Various homeopathic as well as herbal medicines can be used. See treatments under "Proctitis."

Herpes

Probably the most commonly encountered perianal lesion, herpes simplex typically manifests as a burning, searing pain that may be confused with that of a rectal fissure. Examination reveals vesicles on an erythematous base that soon erode and form ulcerations. In patients with HIV or other immunocompromising conditions, the lesions can form deep ulcerations and have a prolonged course. Diagnosis is by Tzanck smear or viral culture.

Initially, treatment protocols should address the current eruption, because longer-term prevention strategies usually take time to work. Topical preparations consisting of deglycyrrhized licorice (DGL) and *Melissa officinalis* extracts can help alleviate local symptoms of burning and pain as well as facilitate the healing process. Zinc sulfate 2% has also been used topically with some success. Various homeopathic medicines not only address the pain and eruptions but also help decrease the patient's susceptibility to further outbreaks. Stress reduction is important as well because herpes eruptions often occur during periods of excessive stress or other illness.

Long-term strategies include decreasing the arginine-containing foods in the diet, such as nuts, legumes (especially peanuts), and chocolate. Supplementing lysine at 500 to 1000 mg/day is useful in eliminating outbreaks. Antioxidants such as vitamins C and E as well as B complex vitamins, zinc, and copper have all been shown to be of benefit.

Pilonidal Sinus

Pilonidal sinus is a rare congenital tract that runs from the coccyx or sacrum to the perineum with constant drainage. Both congenital and acquired factors play a role in the development of a pilonidal sinus. The condition is most commonly seen in young white adults, rarely in black persons, and almost never in Asians. Congenital postanal dimples predispose to the formation of a pilonidal tract as well as obesity, a deep intergluteal cleft, and excess body hair.

The condition is usually differentiated from anal fistula and furunculosis because of its midline orientation and through the passing of a probe through the sinus, noting its passage toward the sacrum rather than the anus.

Patients seek treatment because of the often chronic nature of the discharge. If the sinus becomes infected, incision and drainage may be needed, but irrigation with the herbal formula mentioned for abscess can be performed. Weight reduction and removal of excess hair in the region also helps reduce the risk of infection and symptoms. Homeopathic medicines selected according to the presentation, such as silicea, calcarea sulphuricum, and hepar sulphuris, have proved useful. Additionally, homeopathic *Thuja* as an intercurrent treatment has resolved a number of obstinate cases.

Proctalgia Fugax

Proctalgia fugax, or levator spasm syndrome, is more common in men than women and manifests as an often searing pain near the coccyx or rectum that lasts for a brief but intense period, usually resolving on its own. The episode often wakens the person from sleep but may occur at any time.

Caused by a spasm of the levator ani or pubococcygeal muscle, proctalgia fugax produces a deep-seated, often heavy aching or searing pain that feels as if it were localized in the rectum and/or prostate in men. Examination reveals a tense and tight levator ani muscle that is tender with pressure and is often drawn up above the anal sphincter.

Mechanisms that are thought to trigger an episode are poor posture, chronic anxiety, and mental fixation on the rectal area as well as misalignment of the coccyx or other bones composing the pelvic bowl.

Differential diagnosis includes lumbar disc disease, coccygodynia, prostatitis, presacral tumor, developing ischiorectal abscess, spinal cord tumor, and rectal lesion.

Treatment often takes the form of reassuring the patient as to the etiology of the condition. Muscle relaxants and hot packs may be of benefit. Spinal and pelvic bone adjustments may also be of use, as is massage to the lower abdomen, lumbosacral spine, and perineum. Chronic cases often respond to deep tissue work such as Rolfing.

Proctitis

Proctitis usually manifests as rectal pain, tenesmus, rectal discharge, and blood in the stool. White blood cells may be present in large numbers, being evident on wet preparation, Gram stain, or Wright stain. Because there are a variety of causes for the inflammation, an anoscopic examination is warranted to examine the rectum for inflammation, mucopurulent discharge, mucosal friability, bleeding, and ulceration. Severe ulceration and bleeding are associated with infection by the LGV *Chlamydia* serotype.

Among the causative agents are *Chlamydia* (usually of the genital immunotypes but also the LGV immunotypes), yeast, bacteria such as *Neisseria gonorrhoeae*, parasites, trauma, lectins, excessive fiber in the diet, external irradiation, syphilis, *Trichomonas*, and Crohn's disease. One study demonstrated a higher risk for development of ulcerative proctitis in smokers and persons who had had an appendectomy.[45]

Determination of the etiologic agent dictates the course of treatment and expected outcomes. If the cause is external-beam irradiation for colon cancer or radium seed implants for prostate cancer, the therapy should commence before cancer treatment and continue during it and for several weeks after treatment has ceased. In a study examining the effects of radiation and antioxidant therapy,[46]

it was demonstrated that a "substantial number of patients with radiation proctitis seem to benefit from antioxidant therapy." Despite admonitions by radiation oncologists that antioxidant therapy should be discontinued, a review by Lamson and Brignall[47,48] demonstrated no ill effects when radiation was combined with antioxidant therapy. As part of the therapeutic regimen for radiation proctitis, concomitant administration of homeopathic radium bromatum 200c before and after treatment helps decrease skin burning. Other homeopathic medicines may also be indicated, such as X-Ray, Sol, and cadmium metallicum.

Additionally, the use of demulcent rectal suppositories helps soothe the inflamed rectal mucosa and decrease pain.

If the proctitis is secondary to an inflammatory bowel condition, treatment of the underlying disease results in healing of the rectum as well. This can be accomplished by addressing the patient's diet, providing adequate fiber, and administering herbal demulcents and enteric-coated peppermint to soothe the inflamed intestinal tract. Short-chain fatty acids administered rectally were shown in one study to alleviate symptoms of proctocolitis, and a deficiency of such acids should be considered as part of the clinical presentation.[49,50]

In cases in which an infective agent such as bacteria, *Chlamydia*, yeast, fungi, trichomonas, or a parasite is identified as the etiologic agent, a variety of naturopathic treatments have been found empirically to be effective. Among them are injection of ozone, use of herbal suppositories, homeopathic medicines, and a retention enema consisting of *Hydrastis*, *Usnea*, *Echinacea*, yarrow for *Trichomonas*, and *Althea* in a base of 0.9% NaCl. This combination can be applied topically during the initial examination to begin treatment. Antioxidants such as vitamins C and E, as previously mentioned, facilitate healing.

As a general rule, treatment of proctitis should continue for 10 to 14 days before reexamination and assessment. In cases of ulcerative disease, treatment may need to be continued longer to allow for complete healing.

Pruritus Ani

Pruritus ani is characterized by chronic itching of the perianal skin with excoriation from scratching and an eventual thickening of chronically affected areas. Patients often scratch at night during sleep or are awakened from sleep by the itching. Patients may complain of intermittent to constant itching, burning, and soreness that often awake them at night. Use of topical ointments may provide some relief, but symptoms return when they wear off. Examination may show varying degrees of erythema, swelling, excoriation, thickening, and fissuring due to scratching.

The stage is set for development of pruritus ani when the normal skin protective barriers have broken down. Various agents contribute to this process, such as excessive wiping with harsh toilet papers; use of "wipes" that are impregnated with drying alcohol, dyes, and antibacterial or fungal agents; reactions to synthetic undergarments or detergents used to launder them; and the wearing of too tight underclothing, which decreases air circulation. Patients with chronic diarrhea or loose stools are at increased risk because of the stools' often acidic nature.[51,52] In some cases, removal of normal hair growth for cosmetic purposes also contributes because it disrupts the normal bacterial flora in this region of the body.

Pinworms and *Candida* are the two most common infecting agents in pruritus ani. In particular, a history of perianal itching largely at night should alert the physician to the possibility of *Enterobius vermicularis* infestation (pinworms). This is a common etiologic agent in children and can be spread to other members of the family with considerable ease. A wet preparation will demonstrate *Candida*, and a clear adhesive tape preparation for pinworms helps establish the diagnosis.

Patients with episodes of periodic or chronic diarrhea are also at increased risk of pruritus ani. It can occur because of the acidic nature of the stool but most often is due to aggressive cleaning of the area afterward. Compulsive cleaners should be instructed on the use of cotton wipes, bath or shower cleansing, or the use of moist towels.

The frequent use of soaps, detergents, bleaches dyes, or perfumes can also contribute to the development of pruritus ani. A recent onset may be due to a change in a product, and the physician should ask about it. Certain foods that frequently aggravate the condition are peanuts, coffee, colas, beer, and spicy foods.[5,20] Highly acidic foods and foods that are responsible for an allergic reaction in the patient should be suspected and eliminated for several weeks.

Psoriasis, contact dermatitis, precancerous or cancerous lesions, Bowen's disease (interepithelial epithelioma), keratoacanthoma, melanoma, squamous cell carcinoma, and basal cell carcinoma can also cause pruritus ani.

Laboratory tests to consider are culture and sensitivity testing if bacterial infection is suspected, a potassium hydroxide and/or wet preparation to look for yeast or fungi, Wood's lamp examination for *Tinea cruris*, and a punch biopsy for suspicious lesions.[53]

TREATMENT OPTIONS

Treatment options in anorectal disorders include elimination of spicy or offending foods or of food allergies and improvement of the patient's digestion. If an infective agent is identified, a course of topical therapy to remove the yeast, fungi, or bacteria should be initiated. Initial washing with 3% hydrogen peroxide followed by application of a topical herbal formula containing *Usnea*, *Hydrastis*, *Spilanthes*, oregano, and tea tree oil, which is then allowed to dry, helps eliminate the infective agents. In order to reestablish the skin's defensive barrier, this step should be followed by a healing salve containing *Calendula*, comfrey, and vitamins E and A. Relief should be obtained within 7 to 10 days if the underlying cause has been eliminated.

For pinworms, numerous naturopathic treatments have proved to be effective. Additionally, all clothing and bedding should be washed in warm to hot water to eliminate the eggs that have been laid outside the rectum at night.

Various homeopathic medicines are also effective and may help prevent future episodes in chronic cases. Having the patient use moist cotton wipes after stool and eliminating excess moisture in the perineal area helps break the circle. Topical application of zinc oxide also has proved effective in the treatment of pruritus ani.

Botanicals

Botanical medicines have been used in the treatment of anorectal diseases throughout history by many different cultures. Many of the plants used by the various folk traditions are of the same genus, varying by species only, whereas others are unique to their locations. More recent examinations of the various botanical medicines have elicited their chemical properties and actions, but the eclectic and herbalist traditions have also placed an importance on the symptom specificity of the medicine. Doing so enhances its healing effect.

Aesculus hippocastanum is classified as a tonic, astringent, febrifuge, narcotic, and antiseptic. High in tannic acid and aesculin, this herbal medicine is good for pain relief of internal viscera and is indicated for hemorrhoids and rectal irritation when there is marked congestion and a sense of spasmodic closing of the rectum

as if there were a foreign body present. Additionally, it is effective for itching, a sensation of heat, aching, and rectal pains. It has also been found to be useful for rectal neuralgia and proctitis.[38]

Achillea millefolium (yarrow) possesses slightly astringent properties as well as being an alterative and diuretic. It acts as a tonic on mucous membranes to stem the flow of mild hemorrhage; thus is used for bleeding hemorrhoids, especially if they are accompanied by mucoid discharges.[38]

Althea officinalis (marsh mallow) is high in mucilage, which helps restore the electrical charge to inflamed rectal mucosa. It is often put into rectal suppositories because of its ability to decrease swelling, irritation, and inflammation.[38]

Cinnamomum (cinnamon) is commonly found in herbal rectal suppositories because of its ability to stem hemorrhaging.[38]

Collinsonia canadensis (stone root) is an alterative, tonic, stimulant, and diuretic. It is used primarily for its effects on the venous system because it tones vascular tissue. It is especially indicated for hemorrhoids due to chronic constipation and venous insufficiency. Patients so affected have a sense of constriction, weight, and heat in the rectum and pass very dry stools. It is also useful for proctitis, anal fistulas, and rectal ulcer.[38]

Hamamelis virginiana (witch hazel) is primarily a tonic and astringent. It affects the venous system by restoring vascular integrity; therefore it is an excellent medicine for varicose veins, hemorrhages, and hemorrhoids. Indications for its use are venous tissues that are pale and in varying states of flaccidity but may also possess a deep redness because of vascular engorgement and stagnation of blood flow. The hemorrhoidal tissues are usually very painful and may have a tendency to ulceration.[38]

Hydrastis canadensis (goldenseal) contains hydrastine, berberine, canadine, and acrid resins. It exerts its action upon the mucous membranes and affects the healing of ulcerations while controlling mild hemorrhages; it also has antibacterial properties. Additionally, it has an astringent effect upon hemorrhoids. Goldenseal is indicated for hemorrhoids due to constipation with a sinking feeling in the stomach and a dull headache and for anal fissures that are painful with severe burning before, during, and after stool.[9,54]

Ruscus aculeatus (butcher's broom) acts upon the venous system, where it reduces swelling and has a vasoconstrictive action, thus reducing bleeding.[55]

Homeopathic Medicines

Various homeopathic medicines have historically been used in the treatment of anorectal diseases. Often a few key symptoms manifesting during the initial consultation guide the practitioner to the correct medicine, thus decreasing the need to take a full constitutional case.

TREATMENT SUMMARY FOR HEMORRHOIDS

As with all diseases, the primary treatment for hemorrhoids is prevention. This goal involves reducing the factors that may be responsible for increasing pelvic congestion; straining during defecation, sitting or standing for prolonged periods of time, or underlying liver disease. A high-fiber diet is crucial for the maintenance of proper bowel activity. Fiber supplements, flavonoids, and various botanical medicines such as butcher's broom are appropriate supplementary measures.

Warm sitz baths and topical preparations are useful to ameliorate the discomfort, but have only temporary effects.

Diet

A high-complex-carbohydrate diet rich in dietary fiber is recommended. The diet should contain liberal amounts of flavonoid-rich foods, such as blackberries, citrus fruits, cherries, and blueberries to strengthen vein structures.

Nutritional Supplements

- Psyllium seed husks: 5 g at bedtime
- Vitamin C: 500-1000 mg three times a day
- Flavonoids (choose one of the following):
 - Citrus bioflavonoids, rutin, and/or hesperidin: 3000-6000 mg/ day
 - Micronized diosmin: 500 to 1000 mg/day
 - Grape seed extract: (95% procyanidolic oligomers) 150-300 mg/day
 - Pine bark extract: 150 to 300 mg /day

Botanical Medicine

- Butcher's broom (*Ruscus aculeatus*) extract (9%-11% ruscogenin content): 100 mg three times a day

Physical Medicine

- Hydrotherapy: warm sitz baths to relieve uncomplicated hemorrhoids

DIAGNOSTIC SUMMARY

- Circumscribed red, thickened plaques overlying silvery-white scale.
- Characteristically involves the scalp; the extensor surfaces of the wrists, elbows, knees, buttocks, and ankles; and sites of repeated trauma.
- Positive family history in 30% of cases.
- Nail involvement results in characteristic pitting. Other nail changes include onycholysis, discoloration, thickening, and dystrophy.
- Possible arthritis.

GENERAL CONSIDERATIONS

Psoriasis is a common skin disorder. Its rate of occurrence in the United States is between 2% and 4% of the population. Psoriasis affects few black people in tropical zones but is more common among those in temperate zones, though still lower than for whites. It appears commonly among Japanese but is rare in American Indians. Psoriasis occurs in men and women equally, and the mean onset is at 33 years of age,[1] although 2% of patients show onset by 2 years of age.

Psoriasis is a classic example of a hyperproliferative skin disorder. The rate of keratinocyte proliferation, assessed by proliferating cell nuclear antigen staining, is highest in verrucae (72.1%) and psoriasis (45%), followed by squamous cell carcinoma (28%), actinic keratosis (23%), and basal cell carcinoma (21.4%). The apoptosis inhibitor survivin is a recently described member of the "inhibitor of apoptosis" family expressed in most human cancers and also known to be a regulator of mitosis. Survivin has been detected in 88% of patients with psoriasis. It is likely that other factors are also involved in the development of a hyperplastic epidermis.[2]

The pathogenesis of psoriasis is incompletely understood; it is a complex, multifactorial disease with a genetic predisposition. The etiopathogenicity of psoriasis can be examined from several different viewpoints. It is a polygenic disorder. Oxidative stress has been linked to the inflammation in psoriasis.[3] It is an immune dysfunction. Angiogenesis plays a critical role. Neuropeptides are involved.[4] Research into each of these factors reveals increasing levels of sophisticated studies. At this time, it does not seem possible to combine them all under one unifying theory.

Nevertheless, recent genetic and immunologic advances have greatly increased the understanding of psoriasis as a chronic, immune-mediated inflammatory disorder. The primary immune defect in psoriasis appears to be an increase in cell signaling via chemokines and cytokines that act on upregulated gene expression and cause the hyperproliferation of keratinocytes. Current knowledge of psoriasis has catalyzed the development of targeted biological treatments.

HLA-Cw6, which lies in the major histocompatibility region on chromosome 6, is currently considered the major genetic determinant of psoriasis. Variants in or near genes that encode subunits of cytokines (IL12B, IL23A) or cytokine receptors (IL23R) are of interest. The gene product of IL12B, p40, is the target of a recently approved monoclonal antibody therapy for psoriasis (ustekinumab). Association with psoriasis has also been found in genes coding for tumor necrosis factor-alpha (TNF-α) and other cytokines. Many of these genetic variations are also associated with immune disorders considered psoriatic comorbidities, including Crohn's disease and diabetes.[5]

Although in the past psoriasis was considered a disorder of keratinocytes, it is now generally accepted that it is primarily an immune-mediated disorder. The cells of the

skin consist of cytokine-synthesizing keratinocytes, antigen presenting cells, epidermotrophic and circulating T lymphocytes, dermal capillary endothelial cells, mast cells, tissue macrophages, granulocytes, fibroblasts, and non-Langerhan cells. These cells all communicate by means of cytokine secretion and respond accordingly via stimulation by bacteria, chemical, ultraviolet light, and other irritating factors. The primary cytokine released in response to antigen presentation is TNF-α. Ordinarily this is a controlled process unless the insult to the skin is prolonged, in which case an imbalanced cytokine production in a susceptible host leads to a pathologic state such as psoriasis. Studies have shown that activated keratinocytes in psoriatic lesions not only undergo accelerated turnover but also are a major source of proangiogenic cytokines, such as vascular endothelial growth factor (VEGF), endothelial-cell stimulating angiogenesis factor, TNF-α, and platelet-derived growth factor (PDGF).[6] Other angiogenic mediators—such as hypoxia-inducible factors, angiopoietins, interleukin-8 (IL-8), and IL-17—are upregulated in psoriasis.[7] Patients with psoriasis receiving anti-VEGF treatment for cancer showed complete remission of their cutaneous symptoms.[8]

Initially, immature dendritic cells in the epidermis stimulate T cells from lymph nodes in response to antigen stimulation. The lymphocytic infiltrate in psoriasis comprises predominately CD4 and CD8 T cells. Adhesion molecules that promote leukocyte adherence are highly expressed in psoriatic lesions.[9] After T cells receive primary stimulation and activation, a resulting synthesis of mRNA for IL-2 occurs, resulting in a subsequent increase in IL-2 receptors. The increased IL-2 from activated T cells and IL-12 from Langerhans cells ultimately regulate genes that code for the transcription of cytokines, such as IFN-gamma, TNF- α, and IL-2, which are responsible for the differentiation, maturation, and proliferation of T cells into memory effector cells. Ultimately, T cells migrate to the skin, where they accumulate around dermal blood vessels, producing proangiogenic cytokines and other angiogenic factors as described above. These are the first in a series of immunologic changes that result in the formation of acute psoriatic lesions.[10] The above-described immune response is a somewhat normal response to antigen stimulation. It remains unclear why the T-cell activation that occurs, followed by subsequent migration of leukocytes into the epidermis and dermis, creates accelerated cellular proliferation. One factor that contributes to this is fibronectin (FN), a cell adhesion molecule that anchors cells to collagen or proteoglycan substrates and is involved in many cellular processes, including tissue repair, embryogenesis, blood clotting, and cell migration/adhesion. Transforming growth factor beta (TGF-β) stimulates extra domain A-FN (EDA-FN), a form of FN with an additional domain domain. EDA-FN in turn stimulates keratinocyte hyperproliferation, and through stimulation of Toll-like receptor (TLR) 4, produces proinflammatory cytokines such as TNF-α, IL-1, IL-6, and IL-12. These FN loops contribute to the maintenance and progression of psoriatic lesions. Although the association between psoriasis and cardiovascular disease remains somewhat unclear, one plausible link may be the promotion of atherosclerosis and thrombotic heart disease by EDA-FN.[11]

In summary, it is now recognized that psoriasis is caused by abnormal reactivity of specific T cells in the skin. Alterations in the epidermal barrier, innate defenses, and processing of inflammatory signals may all contribute to the triggering of a nonspecific innate immune mechanism, which, in combination with IL-23 signaling, may lead to the dysregulation of T-cell–driven immune responses.

It is known that psoriasis develops in bone marrow transplant recipients from donors with psoriasis, clears in recipients from donors without psoriasis, and that immunosuppressive drugs are effective in reducing psoriasis.[12,13] Given the genetic predisposition to this disease, what can be done to reduce the phenotypic expression besides resorting to immunosuppressive and biological therapies with their attendant side-effect profiles?

It is interesting that researchers have recognized "unidentified antigens" as ostensibly the source of the psoriatic cascade. A clear relationship of psoriasis with conditions like celiac disease[14] and Crohn's disease[15] has been reported. Furthermore, the bowel mucosa of psoriatic patients without bowel symptoms have shown microscopic lesions and greater intestinal permeability, even when the mucosa appeared macroscopically normal.[16,17] Given information regarding bowel toxemias, food allergies, low proteolytic and bile enzymes, as well as suboptimal liver function and food allergies (see the following sections), a plausible naturopathic suggestion here would be to consider that factors leading to poor intestinal function most likely encourage greater intestinal permeability and inflammation, which ultimately allow these antigenic and endotoxic compounds to leave the intestinal confines, travel through the bloodstream, and initiate activated immune cascades in susceptible tissues.

THERAPEUTIC CONSIDERATIONS

Although psoriasis has a significant genetic component, a decrease in the source of blood-borne antigenic immune activators can be substantially achieved through natural medicine intervention. A number of controllable factors appear to cause or contribute to etiologic bases and pathogenesis of psoriasis, as follows:

- Incomplete protein digestion
- Bowel toxemia
- Impaired liver function
- Bile deficiencies
- Alcohol consumption
- Excessive consumption of animal fats
- Nutritional deficiencies
- Stress

Gastrointestinal Function

Incomplete Protein Digestion

Incomplete protein digestion or poor intestinal absorption of protein breakdown products can result in elevations of amino acids and polypeptides in the bowel. These are metabolized by bowel bacteria into several toxic compounds. The toxic metabolites of the amino acids arginine and ornithine are known as polyamines (e.g., putrescine, spermidine, and cadaverine) and have been shown to be higher in individuals with psoriasis. Polyamines inhibit the formation of cyclic adenosine monophosphate and therefore contribute to the excessive rate of cell proliferation (Figure 204-1).[18-20] Lowered skin and urinary levels of polyamines are associated with clinical improvement in psoriasis.[18]

A number of natural compounds can inhibit the formation of polyamines and may be of benefit in the treatment of psoriasis. For example, vitamin A and the alkaloids of *Hydrastis canadensis* (goldenseal) such as berberine inhibit bacterial decarboxylase, the enzyme that converts amino acids into polyamines.[21,22] However, the best way to prevent the excessive formation of polyamines is to evaluate digestive function with the aid of Heidelberg Gastric Analysis and/or a comprehensive digestive stool analysis and then take the action necessary (e.g., hydrochloric acid supplementation) to ensure complete protein digestion and absorption (these assessment methods can be found in Chapters 18 and 27).

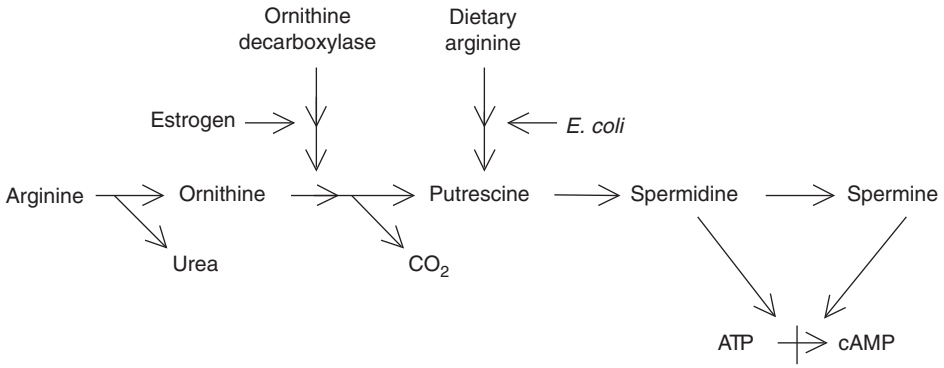

FIGURE 204-1 Amino acids, polyamines, and inhibition of adenylate cyclase.

Bowel Toxemia

A number of gut-derived toxins are implicated in the development of psoriasis, including endotoxins (cell-wall components of gram-negative bacteria), streptococcal products, *Candida albicans,* yeast compounds, and immunoglobulin (Ig) E and IgA immune complexes.[23-25] Endotoxins have been found in high levels in the blood of psoriatic patients,[26] and these compounds lead to increases in cyclic guanosine monophosphate (GMP) levels within skin cells, thereby increasing the rate of proliferation dramatically. Overgrowth of *C. albicans* in the intestines (chronic candidiasis) may play a role in some patients with psoriasis.

A diet low in dietary fiber is associated with increased levels of gut-derived toxins.[23] Dietary fiber is critical to maintaining a healthy colon. Many fiber components bind bowel toxins and promote their excretion in the feces. It is therefore essential that the diet of an individual with psoriasis be rich in beans, fruits, and vegetables. Natural compounds that bind endotoxins and promote their excretion may also be used. For example, an aqueous extract of the herb *Smilax sarsaparilla* was found in a 1942 study to be effective in psoriasis, particularly the more chronic, large plaque–forming variety.[27] In this controlled study of 92 patients, *S. sarsaparilla* greatly improved the psoriasis in 62% of the patients and resulted in complete clearance in another 18% (i.e., 80% of the subjects experienced significant benefits). This benefit is apparently due to *S. sarsaparilla*'s components' binding to and promoting the excretion of bacterial endotoxins.

Because clinical severity as well as therapeutic response have been shown to correlate well with the level of circulating endotoxins, control of gut-derived toxins is important in the treatment of psoriasis. An effort should be made to promote proper binding and elimination of these compounds through support of their excretion in the feces as well as proper handling of absorbed endotoxins by the liver.

Liver Function

The correction of abnormal liver function may be of benefit in the treatment of psoriasis.[28] The connection between the liver and psoriasis relates to one of the liver's basic tasks—filtering and detoxifying the blood returning through the portal circulation from the bowels. Structurally, the hepatic architecture may already be altered in psoriatic patients.[29] As mentioned previously, psoriasis has been linked to the presence of several microbial by-products in the blood. If hepatic function is compromised by excessive levels of these toxins from the bowel or if there is a decrease in the liver's detoxification ability, the systemic toxin level rises and the psoriasis worsens.

Alcohol consumption is known to significantly worsen psoriasis.[30] Alcohol has this effect because it both increases the absorption of toxins from the gut (by damaging the gut mucosa) and impairs liver function. Alcohol intake must be restricted in individuals with psoriasis.

Silymarin, the flavonoid component of *Silybum marianum*, has been reported to be of value in the treatment of psoriasis.[28] Presumably this is a result of its ability to improve liver function, inhibit inflammation, and reduce excessive cellular proliferation.[31,32]

Bile Deficiencies

In the psoriatic patient, endotoxins are able to translocate from the intestine into the bloodstream.[26] Bile acids normally present in the intestines act to detoxify bacterial endotoxins. In the absence of sufficient amounts of bile acids, endotoxins translocating into the bloodstream can produce pathologic conditions that vary in severity depending on their amount, including the release of inflammatory cytokines known to play a role in psoriasis.

A fascinating Hungarian study of 800 psoriatic patients was conducted in which 551 were treated with oral bile acid (dehydrocholic acid) supplementation for 1 to 6 weeks or 3 to 8 weeks for acute or chronic cases, respectively. Conventional therapies were administered to 249 patients as a comparison group. Both groups were advised to eat a diet high in vegetables and fruits and were instructed to avoid hot spices, alcohol, raw onion, garlic, and carbonated soft drinks. Of the 551 patients receiving bile acid, 434 (78.8%) became asymptomatic, whereas only 62 (24.9%) of the 249 patients receiving conventional therapies demonstrated clinical recovery during this treatment period. Additionally, the curative effect of bile acid supplementation was more pronounced in the acute form of psoriasis; 95.1% of the patients in this group became asymptomatic. In follow-up assessments 2 years later, 319 of the 551 patients with acute and chronic psoriasis who had been treated with bile acid (57.9%) were asymptomatic, compared with only 15 of the 249 patients (6%) who had received the conventional treatment.[26] The bile acid supplements used in the preceding study were either 2 or 3 dehydrocholate sodium (Suprachol) sugar-coated pills once a day or dehydrocholic acid powder (acidum dehydrocholicum pulvis) at two to three doses of 0.25 g/day.

Because there is a theoretical risk of malignant tumors in patients with sluggish intestinal function given long-term bile acid therapy, the investigators in this study recommended that their subjects not continue ingesting bile acids on a regular basis but to supplement with them only after a fatty meal once the initial treatment period had been completed. Two separate evaluations of bile acid effects on the proliferation of colonic mucosa report conflicting results.[33,34] Two other studies actually found a cancer-protective effect of ursodeoxycholic acid. One was an observational study of 114 patients with primary biliary cirrhosis in whom a reduction in the risk for colon adenoma was discovered. The prevalence of

colorectal adenomas was 13% in the treated group versus 24% in the untreated group. Additionally, the colon epithelial cell proliferation index was significantly lower in treated patients than in untreated patients.[35] A second randomized controlled clinical trial of 52 subjects found significant declines in the risk for developing colorectal dysplasia or cancer in patients with ulcerative colitis and primary sclerosing cholangitis.[36] More clinical research is needed to examine the different varieties of bile acids and their efficacy as well as their safety profile. Nevertheless, given the preceding information, it seems reasonable to consider the use of bile acids for the short-term treatment of psoriasis and to monitor the colon before and after treatment in patients at high risk for colon cancer.

Nutrition

Omega-3 Fatty Acids

The manipulation of dietary oils is extremely important in the management of psoriasis because serum levels of free fatty acids are typically abnormal in affected patients.[37] Of particular benefit are the omega-3 fatty acids. Most of the clinical research has utilized fish oils rich in eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Several double-blind clinical studies have demonstrated that supplementing the diet with 10 to 12 g/day of fish oils (providing 1.8 g EPA and 1.2 g DHA) results in significant improvement.[38-40] This amount of EPA and DHA would be equivalent to the amount of EPA in about 150 g of salmon, mackerel, or herring.

The improvement in psoriasis from EPA is partly due to the competition of EPA for arachidonic acid binding sites, producing leukotriene B5 (LTB5), which is only one tenth as potent as the inflammatory mediator LTB4. Levels of LTB4 have been shown to be elevated in psoriatic plaques and to demonstrate chemotactic properties necessary for the infiltration of leukocytes and the proliferation of keratinocytes.[41] In the skin of individuals with psoriasis, the production of inflammatory leukotrienes from arachidonic acid is many times greater than normal.[42] Leukotrienes are potent inflammatory agents and promoters of guanylate cyclase activity.

In the psoriatic epidermis, the cellular contents of free arachidonic acid and 12-hydroxyeicosatetraenoic acid (12-HETE; a product of lipoxygenase metabolism of arachidonic acid) are 250 and 810 times greater, respectively, than in uninvolved epidermal tissue.[42]

Immunomodulatory effects of omega-3 fatty acids include the suppression of lymphocyte proliferation, CD4 cells, antigen presentation, adhesion molecule presentation, Th1 and Th2 responses, and proinflammatory cytokine production (such as IL-1, TNF-α, and PDGF), which prevents vascularization within the psoriatic plaque.[43]

Trauma also induces the release of free arachidonic acid and may account for the common clinical observation of plaques at the sites of repeated trauma. These observations are significant, because the increase in 12-HETE stimulates the 5-lipoxygenase pathway, promoting leukotriene formation. This pathway is inhibited by EPA and glutathione peroxidase, suggesting that a selenium deficiency may be a contributory factor (see later "Diet, Fasting, and Food Allergy Control")

As might be expected, cyclooxygenase inhibitors (e.g., aspirin and most other nonsteroidal antiinflammatory agents) may exacerbate psoriasis, whereas lipoxygenase inhibitors (e.g., benoxaprofen) may bring improvement.[44] Naturally occurring substances such as quercetin (the ubiquitous plant flavonoid), vitamin E, onion, and garlic are known to inhibit lipoxygenase and therefore may be of benefit. However, it is improbable that selective inhibition of one component or enzyme (e.g., a 5-lipoxygenase inhibitor) would do more than create an imbalance in this closely integrated network of mediators, which may not necessarily be beneficial.[45]

Because arachidonic acid is found only in animal tissues, patients with psoriasis must limit their intake of animal products, particularly animal fats and dairy products.

Diet, Fasting, and Food Allergy Control

An evaluation of 316 patients with psoriasis and 366 control subjects, both groups being in the age range of 16 to 65 years, found that psoriasis was positively associated with body mass index and inversely related to the intake of carrots, tomatoes, fresh fruits, and the index of beta-carotene intake.[46] Research at a Swedish hospital studying the effects of fasting and vegetarian regimens on chronic inflammatory disease found that such diets helped psoriatic patients.[47] The improvement was probably due to decreased levels of gut-derived toxins and polyamines. Patients have also benefited from gluten-free and elimination diets.[48,49] Several herbs used as seasonings—including turmeric, red pepper, cloves, ginger, cumin, anise, fennel, basil, rosemary, garlic and pomegranate—can block the activation of nuclear factor-kappa B of inflammatory cytokines.[50]

Individual Nutrients

Decreased levels of vitamin A and zinc are common in patients with psoriasis.[51-53] Given the critical roles of these nutrients in the health of the skin, supplementation might be warranted even without this association.

Chromium supplementation may be indicated to increase the sensitivity of insulin receptors, because psoriatic patients typically have increased serum levels of both insulin and glucose and carry an increased risk for type 2 diabetes mellitus and metabolic syndrome.[54]

Substantial evidence indicates that psoriasis is an independent risk factor for cardiovascular disease.[55] It remains difficult to conclude whether risk factors are caused by psoriasis or share a common pathogenesis. Inflammation, characterized by the presence of proinflammatory cytokines and endothelial activation, is a common theme underlying these conditions. Dyslipidemia, coronary calcification, increased highly sensitive C-reactive protein, decreased folate, and hyperhomocysteinemia are found significantly more often in psoriatic patients.[56]

The inflammatory processes underlying psoriasis suggest the possibility of omega-3 fatty acid, folate, and vitamin B_{12} deficiencies, which are also found in cardiovascular disease.[57] High homocysteine and decreased folate levels correlate with the psoriasis area and severity index (PASI). The rapid keratinocyte turnover rate in psoriasis may result in folate utilization and subsequent deficiency.[58] The authors of one study conclude that "Dietary supplementation of folic acid, B_6, and B_{12} appears reasonable in psoriasis patients, particularly those with elevated homocysteine, low folate and additional cardiovascular risk factors."[59] In supplementing with folic acid or its active form 5-methyltetrahydrofolate, the recommended dose is 1 to 5 mg/day.

Glutathione peroxidase (GP) levels are low in psoriatic patients, possibly because of such factors as alcohol abuse, malnutrition, and the excessive loss of skin due to the hyperproliferative disease. The depressed levels of GP normalize with oral selenium and vitamin E therapy.[60] One investigation found that patients with longer-term psoriasis (3 years or more) demonstrated low plasma selenium status.[61] Another study comparing 113 patients with moderate to severe psoriasis and 104 healthy controls found that male psoriatic patients between 20 and 49 years of age and women with the disease of longer than 20 years' duration had particularly low selenium concentrations. The lowest whole-blood selenium

values were found in the subgroup of male patients with widespread disease of long duration who also required treatment with methotrexate and retinoids.[62]

It has been established that patients with disseminated psoriasis have significantly decreased serum levels of the biologically active form of vitamin D, 1,25-dihydroxycholecalciferol (calcitriol) compared with age- and gender-matched controls and also compared with patients with moderate psoriasis.[63] Whether this is a contributing factor to psoriasis or a result of the disorder has not been elucidated.

Keratinocytes in the epidermis convert 7-dehydrocholesterol to vitamin D_3 in the presence of ultraviolet B. Sunlight, UVB phototherapy, oral calcitriol, and topical vitamin D and its analogs are effective therapy for psoriasis owing to vitamin D's antiproliferative and prodifferentiating actions on keratinocytes.[64] Vitamin D also encourages a shift toward type 2 helper T-cell cytokine expression, with an increase in IL-10 and a decrease in IL-8, which may be responsible for the improvements seen in psoriasis.[65]

Vitamin D analogs like calcipotriol have also been shown to mediate the expression proinflammatory antimicrobial peptides such as β-defensin and to decrease IL-17A, IL-17F, and IL-8 in lesional psoriatic skin.[66] Topical calcitriol has also been shown to reduce the number of dendritic cells in the skin.[67]

Calcitriol-binding to vitamin D receptors (VDRs) in the skin modulates the expression of a large number of genes including cell-cycle regulators, growth factors, and their receptors. Polymorphisms of the VDR gene are associated with psoriasis and may predispose to the development of psoriasis and resistance to calcipotriol therapy while also contributing to liver dysfunction in patients with psoriasis.[68]

Given the importance of vitamin D in psoriasis, cancer, inflammatory diseases, and other conditions, it has been suggested by some investigators that recommendations for sun protection and skin cancer prevention may need to be reevaluated to allow for sufficient vitamin D status. However, studies conducted in Honolulu, Miami, and southern Arizona showed that abundant sun exposure did not necessary ensure vitamin D adequacy, which points to the need for vitamin D supplementation to achieve optimal blood levels while also protecting the skin from sun damage and skin cancer.[69]

It has been demonstrated that oral vitamin D can be safely taken in daily doses of up to 5000 IU/day, with some experts recommending up to 10,000 IU/day to correct a deficiency.[70]

Fumaric Acid

Over the past three decades, fumaric acid therapy has become increasingly popular in western Europe for psoriasis. Therapy consists of the oral intake of dimethylfumaric acid (240 mg/day) or monoethylfumaric acid (720 mg/day) and the topical application of 1% to 3% of monoethylfumaric acid. Clinical studies have shown that it is useful in many patients with psoriasis,[71] but side effects such as flushing of the skin, nausea, diarrhea, general malaise, gastric pain, and mild liver and kidney disturbances can occur.[72] We recommend using fumaric acid therapy only after other natural therapies have proved ineffective.

Psychological Aspects

Research work concerning the role of stress in psoriatic exacerbations is mixed. One investigation revealed that a large proportion (39%) of patients with psoriasis report the occurrence of a specific stressful event within 1 month before their initial episode. Such patients have a better prognosis.[73] Yet other findings show a limited relationship between stress and vulnerability to psoriasis, whereby correlation seemed to occur mostly in patients with repeated stressors occurring four times or more in 1 year.[74] Stress management can benefit individuals with psoriasis.[75] As judged by two independent dermatologists, subjects who listened to a guided meditation tape while undergoing phototherapy cleared four times as quickly as those who received phototherapy only. Psoriasis status was assessed in three ways: direct inspection by unblinded clinic nurses, direct inspection by physicians blinded to the patient's study condition (tape or no-tape), and blinded physician evaluation of photographs of psoriatic lesions. Four sequential indicators of skin status were monitored during the study: a First Response Point, a Turning Point, a Halfway Point, and a Clearing Point. Subjects in the tape groups reached the Halfway Point ($P = 0.013$) and the Clearing Point ($P = 0.033$) significantly more rapidly than those in the no-tape condition for both UVB and PUVA treatments. Finally, psychotherapy can be an essential adjunct for individuals with persistent unresolved psychological issues such as anxiety, depression, and the psychosocial stress of this chronic skin disease. A few case histories have been reported that document the successful treatment of psoriasis with hypnosis and biofeedback alone.[76]

Physical Therapeutics

Sunlight and Ultraviolet Light

Sunlight (which contains ultraviolet light) is extremely beneficial for individuals with psoriasis.[77,78] Outdoor 4-week heliotherapy was shown to promote significant clearance of psoriatic symptoms in 84% of 373 subjects.[79] Studies employing nonprescription commercial tanning beds have shown that a majority of patients find them helpful[80]; they also objectively facilitate improvements in both psoriasis severity and health-related quality of life.[81] In addition, an open-label retrospective trial studied the combined use of the retinoid acitretin (a vitamin A derivative) along with a 4- to 5-day-per-week tanning regimen; 83% of 23 subjects experienced complete or near-complete recovery.[82]

Specific ultraviolet exposure may also be of benefit owing to its induction of vitamin D synthesis in the skin. The standard ultraviolet medical treatment of psoriasis typically involves the use of the drug psoralen and ultraviolet A (PUVA therapy; 320 to 340 nm). Ultraviolet B (UVB; 280 to 320 nm) exposure alone also leads to inhibition of cell proliferation; in certain studies, it has been shown to be as effective as PUVA therapy, with fewer side effects.[87] At the Dead Sea, where 80% to 85% of psoriatic conditions clear in 4 weeks, UVB wavelengths are known to be the dominant light.[83,84] In one investigation of 28 patients, UVB had a clear advantage over PUVA therapy.[18] Conversely, another report comparing UVB with PUVA in 100 patients demonstrated clearance of psoriasis in a significantly greater proportion of patients treated with PUVA (84%) than with UVB (63%), and with significantly fewer treatments.[85] Other studies have found both to be effective, with similar untoward side effects.[86,87] It is clear that more study is needed to clarify both the risks and benefits of these therapies and whether certain presentations of psoriasis may respond best to a specific ultraviolet therapy. As noted above, ultraviolet light deactivates vitamin D topical agents, Therefore, if they are used in conjunction, the topical agent should be applied only after ultraviolet treatment. Furthermore, any light therapy should be monitored carefully, especially in patients at risk for skin cancers.

Other Physical Therapeutics

The induction of localized elevation of temperature (42°C to 45°C) to the affected area by ultrasound and heating pads has been shown to be an effective treatment of psoriasis.[88,89] Italian

researchers have conducted small clinical trials using a hypotonic sulfate water (Leopoldine water) in a balneotherapeutic manner. These treatments have yielded favorable immunohistologic profiles of the affected tissues with significant decreases in the numbers of T lymphocytes, Langerhans cells, and markers of keratinocyte inflammatory expression.[90]

Topical Treatments

A number of natural proprietary formulas as well as over-the-counter preparations can be used to provide symptomatic relief in mild to moderate psoriasis.

Aloe vera

A very exciting, double-blind, placebo-controlled study found that topical application of an *A. vera* extract in a hydrophilic cream was highly effective in psoriasis vulgaris. Sixty patients with slight to moderate chronic plaque-type psoriasis and the PASI scores between 4.8 and 16.7 (mean 9.3) whose mean duration of disease averaged 8.5 years (range 1 to 21 years) applied either the aloe or a placebo gel three times a day. The treatment was well tolerated by all the patients, with no adverse drug-related symptoms and no dropouts. By the end of the study (4 to 12 months of treatment), the *A. vera* extract cream had cured 25 of 30 patients (83.3%) compared with the placebo cure rate of only 2 of 30 (6.6%), resulting in significant clearing of the psoriatic plaques (328 of 396 [82.8%] vs. placebo 28 of 366 [7.7%]) and a decrease in PASI score to a mean of 2.2.[91a]

Curcumin

Curcumin gel yielded 90% resolution of plaques in 50% of patients within 2 to 6 weeks; the remainder of the study subjects showed 50% to 85% improvement.[91] Curcumin was found to be twice as effective as calcipotriene cream (which generally takes 3 months to exert its full effect). Curcumin acts as a selective phosphorylase kinase inhibitor, thereby reducing inflammation through the inhibition of NFκB.

Mahonia aquifolium

Several open and placebo-controlled trials have supported the effectiveness of *Mahonia aquifolium* topical cream in the treatment of psoriasis. On the basis of physician and patient assessments, 71% to 81% of patients improved in these trials.[92] A randomized double-blind placebo-controlled trial of 200 patients also demonstrated statistically significant improvement when this agent was applied twice daily for 12 weeks.[93]

Topical Vitamin D

Topical corticosteroids are the most common treatment for psoriasis; however, their long-term use is associated with a potential risk for side effects. Topical vitamin D modulators have been developed as an option for use in place of or in addition to, topical corticosteroids. Topically, vitamin D inhibits keratinocyte proliferation, normalizes differentiation, and modulates immune cell activity with minimal effect on serum calcium.[94] Calcipotriene is the most widely used topical vitamin D. Although evidence suggests that in the long term it is approximately as effective as low- to medium-potency corticosteroids (response is not obtained as quickly as with corticosteroids), it is associated with cutaneous irritation, especially when used on sensitive skin. Calcitriol ointment was recently approved and contains the naturally occurring active form of vitamin D_3 and is associated with a low rate of cutaneous and systemic adverse effects.

By inhibiting proinflammatory cytokines such as IL-12, IL-23, and TNF-α, topical nicotinamide has been shown to enhance the efficacy of calcipotriene therapy when used in combination.[95]

Emollients

The scaliness of psoriasis benefits from the use of emollients. Intercellular lipids such as ceramides play an important role in regulating the homeostasis of the skin water barrier and the skin's water-holding capacity, and it has been shown that ceramides are decreased in the psoriatic epidermis. Newer ceramide-containing emollients (e.g., CeraVe, Mimyx, Aveeno Eczema Care) have shown benefit in psoriasis and may improve skin barrier function and decrease water loss.[96]

THERAPEUTIC APPROACH

Despite the complexity of this disease, the therapeutic approach is fairly straightforward: decrease bowel toxemia, rebalance fatty acid levels and inflammatory processes systemically and in the skin, and use the listed therapeutic regimen to further balance the abnormal cell proliferation.

Diet

- Limit sugar, meat, animal fats, and alcohol.
- Increase intake of dietary fiber and cold-water fish and, if indicated, bring weight to normal levels.
- Eliminate sources of gluten if patient is gluten-sensitive.
- Identify and address any food allergies.

Supplements

- High-potency multivitamin/multimineral formula.
- Fish Oils: 3000 mg EPA+DHA
- Vitamin D: 5000 to 10,000 IU/day based on serum 25(OH)D level.
- Consider vitamin E 400 IU/day, chromium 400 mcg/day, selenium 200 mcg/day, zinc 30 mg/day.
- Consider digestive enzymes and/or bile acids with meals.
- Water-soluble fiber (psyllium, pectin, guar gum, etc.): 5 g at bedtime.

Botanical Medicines

Consider the following if indicated by impaired digestion or liver function:

H. canadensis (goldenseal):
- The dose should be based on berberine content, because there is a wide range of quality in goldenseal preparations, standardized extracts are preferred three times a day.
- Dried root or as infusion (tea): 2 to 4 g three times a day.
- Fluid extract (1:1): 2 to 4 mL (0.5 to 1 tsp) three times a day.
- Solid (powdered dry) extract (4:1 or 8% to 12% alkaloid content): 250 to 500 mg three times a day.

S. sarsaparilla:
- Dried root or by decoction: 1 to 4 g three times a day
- Liquid extract (1:1): 8 to 16 mL (2-4 tsp) three times a day
- Solid extract (4:1): 250 to 500 mg three times a day

S. marianum (milk thistle):
- Silymarin: 70 to 210 mg three times a day

Psychological Considerations

- Evaluate stress levels and use stress reduction techniques as appropriate.

Physical Medicines

- Sunbathing—taking precautions not to become sunburned.
- UVB: 295 to 305 nm, 2 mW/cm^2, 3 minutes, three times a week

Topical Treatment

- *Aloe vera,* curcumin, *Mahonia aquifolium,* or vitamin D. Apply to affected areas of the skin two to three times/day.
- Ceramide-containing emollient two to three times a day.

CHAPTER 205

Rheumatoid Arthritis

Gregory T. Yasuda, ND, LMP, Peter B. Bongiorno, ND, LAc, and Michael T. Murray, ND

DIAGNOSTIC SUMMARY

- Insidious onset of chronic, severe joint pain and inflammation.
- Polyarticular and symmetrical bilaterally.
- Begins in the small joints and progresses to affect other joints in the body.
- A systemic disease: fatigue, low-grade fever, weakness, weight loss, joint stiffness, and vague joint pain may precede the appearance of classic symptoms by weeks or months.
- Extra-articular manifestations include vasculitis, subcutaneous and systemic granulomas, pleurisy, pericarditis, pulmonary fibrosis, lymphadenopathy, splenomegaly, and anemia.
- Serum is usually positive for rheumatoid factor (RF) and/or anti–cyclic citrullinated peptide antibodies (anti-CCP), although no single laboratory test is diagnostic.

GENERAL CONSIDERATIONS

The most common form of inflammatory polyarthritis, rheumatoid arthritis (RA) is a chronic condition with a widely variable course that affects the entire body. Fatigue, low-grade fever, weakness, joint stiffness, and vague joint pain may precede the appearance of joint inflammation by weeks or months, sometimes making early diagnosis difficult.[1] Between 0.3% and 1% of most populations are affected and women outnumber males almost 3:1. Although RA may begin at any age, the usual age at onset is 40 to 50 years.[2]

The onset of RA is usually gradual but occasionally quite abrupt. The joints with the greatest ratio of synovium to articular cartilage are generally most affected: the knees, ankles, feet, wrists, and hands. Any joints may be affected eventually: however, the distal interphalangeal joints are generally spared.[1] Although joint involvement is confined to one or a few joints in about one third of persons, the initial presentation is generally polyarticular and bilaterally symmetrical—both hands, both wrists, or both ankles.[3]

Involved joints characteristically present with inflammation and prolonged morning stiffness. As the disease progresses, bony erosion, subluxations, dislocations, and contractures develop and lead to joint deformities, particularly in the hands and feet. Cervical spine involvement is common and instability of the atlantoaxial joint is a dangerous manifestation owing to the risk of spinal cord compression.[2] Because of joint destruction and commonly prescribed immunosuppressive drugs, rheumatoid arthritis patients are also predisposed to septic arthritis; with a mortality rate as high as 11.5%,[4] this must not be confused with a flare of RA.

Pathogenesis

Although the mechanism that produces the characteristic inflammatory joint destruction has not been elucidated completely, RA is considered an autoimmune condition because it features autoantibody production in most patients. Although the exact triggers of this autoimmune reaction are unknown, RA is far from idiopathic. This appears to be a multifactorial disease in which genetic, environmental, and immunologic factors contribute to the disease process.

Genetic Susceptibility

Female gender and positive family history are considered risk factors for developing RA, and studies of twins demonstrate other genetic risk factors.[1] There is a 15%

concordance rate in monozygotic twins—four times that in dizygotic twins.[2] Genetic studies have isolated a "shared epitope" in HLA-DR1 and -DR4 subtypes that is expressed in 80% of whites with RA.[1]

In addition to susceptibility, genetics also play a role in the disease process. HLA-DRB1 and other factors may be associated with more aggressive disease by affecting antioxidant pathways, detoxification pathways, and other processes that likely contribute to the pathogenesis of RA. Patients with RA also have changes in fecal flora that are thought to contribute to the pathogenesis of the disease (see discussion below), and studies have shown that the flora of monozygotic twins is more similar than that of dizygotic twins independent of other contributing factors.[5]

Environmental Factors

The low penetrance in the genetic studies indicates that environmental factors are contributory. Toxins in cigarette smoke interact with the HLA-DRB1 shared epitope alleles, enhancing the inflammatory process and increasing the risk of seropositive RA.[6] Smokers' risk of developing RA is nearly eightfold for carriers of the shared epitope and nearly sixteenfold for homozygous individuals.[7] Smoking also increases RA risk in the general population, threefold for men, and quitting smoking results in a decreased risk of seropositve disease.[8]

Low socioeconomic status is associated with increased morbidity and mortality in RA.[9] Other factors such as poor diet, drinking more than three cups of coffee per day, silicate exposure, and psychological factors may also play a role in the development of the disease and affect the levels of pain and physical disability experienced by RA patients,[10] whereas oral contraceptives, tea intake, and increased vitamin D consumption have been found to be protective.[1] Other environmental factors such as low temperature, high atmospheric pressure, and high humidity have been correlated with increased RA pain.[11]

Oxidative Stress

Several studies have shown that the risk of RA is highest in people with the lowest levels of nutrient antioxidants. One study examined people who developed RA and systemic lupus erythematosus (SLE) 2 to 15 years after they donated blood in 1974.[12] For each case, four controls were selected from the serum bank donors matched for race, gender, and age. Stored serum samples from cases and controls were assayed for α-tocopherol, beta-carotene, and retinol. Patients with both diseases had lower serum concentrations of α-tocopherol, beta-carotene, and retinol in 1974 than their matched controls. Low antioxidant levels may be exacerbated by genetic factors; the shared epitope leads to increased nitrous oxide production and inhibition of antioxidative cellular pathways.[13] The resulting increase in oxidative stress could produce free radical damage of DNA and mutations that may contribute to the pathogenesis of RA.[14] Once disease is established, synovial concentrations of free radicals are elevated and concentrations of antioxidants are diminished,[15] accelerating inflammation and joint destruction.

Autoantibody Production

The serum of most individuals with RA contains rheumatoid factor (RF) and cyclic citrullinated peptide autoantibodies (anti-CCP); their presence is thought to contribute to the pathogenesis of RA. The serum titers often correlate well with the severity of arthritis symptoms and prognosis, but not in every case, and the antibodies are not directly responsible for joint destruction. Autoantibodies have been detected as long as 10 years prior to the onset of clinical disease, and inflammatory markers—such as soluble tumor necrosis factor receptor II—have been elevated for up to 12 years prior to diagnosis[16] and positively correlated with RA incidence. This suggests a "multiple hit" model[17] in which pathogenesis progresses in distinct stages, perhaps explaining why autoantibodies are present for years before clinical manifestations appear.

Microbial Influences: Infection and Cross-Reactivity

Microorganisms play important roles in states of health and disease, the most obvious being frank infections that facilitate the pathogenesis of RA. The onset of RA is preceded by a specific inciting event, such as an infection, in 8% to 15% of cases,[18] and antimicrobials such as metronidazole,[19] clotrimazole,[20] acyclovir,[21] roxithromycin,[22] tetracycline,[23] sulfasalazine,[24] and minocycline[25] have been associated with improvement in symptoms and, in some cases, complete remission. Many pathogens—such as Epstein-Barr virus, cytomegalovirus, parvovirus, rubella virus, *Mycoplasma,*[1] amebic organisms,[18] *E. coli*,[26] influenza AH2N2,[27] *Porphyromonas,* and *Proteus*—have been associated with RA. Although no single microbial agent has been consistently isolated in patients with the disease, it may be that a multitude of organisms can directly or indirectly contribute to the disease process by infection, antigen persistence, circulating immune complexes, or immune cross-reactivity. This is not unprecedented: reactive arthritis occurs secondary to an enteric, urogenital, or respiratory infection by any of over a dozen different microorganisms in a genetically susceptible individual and persists well beyond—or occurs even in the absence of—any clinically evident infection. The condition becomes chronic in 15% to 60% of cases.[1]

Some organisms, such as parvovirus B19, commonly produce an RA-like arthritis and autoantibodies, including RF and ANA, which may be positive in early infection. Although most patients clear the infection, chronic forms are known in up to 20% of cases, where viral DNA is recoverable from a variety of tissues for years postinfection, raising the possibility that RA development could be driven by chronic infection and/or persistence of parvovirus B19 antigens.[28] Other pathogens, such as *Proteus mirabilis,* stimulate production of cross-reactive antibodies, which were found to be elevated in over 90% of patients with active RA in one study; these antibody levels were positively correlated with markers of disease activity: erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and rheumatoid factor (RF).[29] These antibodies are homologous with type XI collagen found in hyaline cartilage, and their immune complexes have been recovered in the synovia of RA patients.[30] This mechanism of cross-reactivity has been demonstrated with other organisms as well. For example, antibodies to *Campylobacter, Salmonella,* and *Shigella* have been shown to cross-react with collagen, whereas antibodies to *Klebsiella pneumoniae, Proteus vulgaris,* and *Yersinia enterocolitica* cross-react with other joint tissues.[31,32]

Dysbiosis and Small Intestinal Bacterial Overgrowth

Perhaps more important than specific pathogenic organisms is the subtler influence of the commensal microflora on the internal gut environment. There are more microflora in the digestive tract than human cells in the body, and the composition of the hundreds of species of microorganisms is know to be affected by genetics, medical treatment, diet, and stress.[33] The flora have a profound influence on immune function, nutritional status, and stress response and can contribute to many diseases.[34] *Bacteroides thetaiotaomicron,* a member of the normal flora in mice and humans, was inoculated in the GI tracts of germ-free mice. Monitoring the host

transcriptional response to this single species, the researchers observed an unexpected breadth of influence on intestinal function, including improved nutrient absorption and processing by the host, mucosal barrier fortification, influx of IgA-producing B cells, and prevention of the inflammatory response or complement-mediated mucosal damage. Also affected were xenobiotic metabolism, neurotransmitter production, the enteric nervous system, gut motility, angiogenesis, and postnatal intestinal maturation.[35] Many of these intestinal functions are thought to be involved in the pathogenesis of RA.

Fecal flora is significantly altered in RA, including significantly less bifidobacteria and bacteria of the *Bacteroides-Porphyromonas-Prevotella* group[36]; randomized, clinical studies have demonstrated improvement with changes in microbial flora.[37,38] Likewise, many RA patients have small intestinal bacterial overgrowth (SIBO), 51% in one study,[39] and the degree of SIBO was associated with the severity of symptoms and disease activity. Vasquez[40] introduces the concept of multifocal dysbiosis, whereby alteration in normal flora is not confined to the gut and cumulatively can produce immune dysregulation typical of any autoimmune condition. Discussed above was the impact of a single species; the cumulative load of all microflora, the majority of which are uncultivated and novel organisms,[41] is difficult to predict. This concept of total pathogen burden does, however, appear to correlate with increased CRP and cardiovascular risk[42] and may also contribute to the pathogenesis of RA. Evidence to support this concept can be found in patients with concurrent RA and periodontal disease. One study found identical periodontal bacterial DNA in 100% of synovial fluid samples and 83.5% of serum samples of RA patients,[43] and another study found a correlation between the severity of periodontitis and the severity of RA symptoms.[44] Antibodies to *Porphyromonas gingivalis* are associated with elevated anti-CCP antibodies and may be involved in breaking immune tolerance to citrullinated antigens and promoting the autoimmune response in RA.[45]

Adverse Food Reactions

As many as 10% of the population have food allergies[46]; for patients who have tested positive for allergies on skin-prick testing, consumption of those allergenic foods is associated with increases in inflammatory markers such as tumor necrosis factor α (TNF-α), interleukin 1β (IL-1β), CRP, and ESR.[47] Outcomes of food allergy studies in RA have been conflicting. Two possible explanations for negative correlations include that the allergen challenges were too small in quantity, frequency, or both, and that serum antibody levels are not representative of the mucosal immune response in the intestine. Another confounding factor is that adverse food reactions such as food intolerance, sensitivity, and dietary lectins[48] are not antibody-mediated and therefore not apparent with antibody testing; yet, these reactions may be contributory.

One group analyzed the studies that considered the quantitative exposure to allergenic foods and found that studies using larger doses of food antigens tend to provide a positive correlation between RA and food allergies in 20% to 40% of patients.[49] These same authors examined the jejunal and serum antibody secretions of RA patients and compared them with those of controls. Although serum food antibodies were not correlated with RA, jejunal IgA, IgG, and especially IgM were significantly elevated against nearly all food antigens in RA patients compared with controls, and the antibodies were substantially cross-reactive. The investigators concluded that RA patients may have multiple modest hypersensitivity reactions and that the additive effect could lead to widespread antibody-mediated tissue destruction.

Xenobiotics and Autoantibody Production

Xenobiotics appear to intersect with genetics, pathogenic organisms, and other dietary and environmental factors to stimulate autoantibody production and autoimmunity. Certain xenobiotics may be particularly toxic to both RA patients and people at risk for RA owing to impaired metabolism in acetylation pathways. A single genetic risk factor, the N-acetyltransferase 2 polymorphism, affects both the acetylation of xenobiotics and individual susceptibility to RA.[50] It also predicts disease severity: the slow-acetylator genotype is associated with a 4.39 times greater risk of erosive RA than fast types.[51]

Other toxins also appear to induce similar autoimmune responses in genetically susceptible patients. Bacterial toxins, such as streptokinase and heat-shock proteins, can bind to mucosal tissue enzymes and stimulate autoantibody production against peptides and tissue antigens.[52] This same response was also stimulated by gliadin peptides, illustrating that food antigens can elicit responses similar to those caused by bacterial superantigens. Streptokinase, gliadin, casein (a milk protein), and ethyl mercury (the vaccine adjuvant in thimerosal) bind to different lymphocyte receptors and tissue antigens, producing neoantigens that can induce the production of cross-reactive autoantibodies.[53]

Abnormal Gut Permeability

Individuals with RA have greater intestinal permeability to dietary and bacterial antigens as well as alterations in bacterial flora.[54-56] Chronic inflammation in the gut can cause increased intestinal permeability and is associated with joint inflammation.[57] Adverse food reactions and bacterial endotoxins[58] may contribute greatly to chronic gut inflammation; moreover, the nonsteroidal antiinflammatory drugs (NSAIDs) that are commonly prescribed for RA can also exacerbate this.[59] However, increased gut inflammation and permeability also occur in RA independent of NSAID use.[60] This "leaky gut" facilitates the translocation of dietary and gut-derived antigens[9,57] and bacterial gut flora to blood, mesenteric lymph nodes, the spleen, and the kidneys.[61] In conjunction with dysbiosis and bacterial overgrowth, increased gut permeability to bacterial endotoxins and food antigens can produce immune activation and circulating immune complexes, many of which have been recovered in synovial fluid and could contribute to joint inflammation and degeneration.

Decreased Androgen Levels

Androgens and progesterone are natural immune suppressors and appear to be involved in the apoptosis of activated immune cells.[62] Chronically low levels of testosterone and dehydroepiandrosterone (DHEA), a known inhibitor of cytokines owing to nuclear factor-kappa B inhibition, have been found in early-stage and established RA.[63-65] A small study showed positive effects of testosterone replacement therapy in male RA patients, decreasing RF titers, the number of affected joints, and NSAID use.[66] Although DHEA at 200 mg/day was found to be effective for SLE in a randomized, controlled trial,[67] another small open-label trial involving 11 elderly patients with RA who were taking antirheumatic drugs found little benefit from supplementing with DHEA at the same dose.[68] DHEA and testosterone may have to be modulated in concert with estrogens to be optimally effective in RA. Chronic inflammation and elevated TNF-α promote conversion of testosterone to estrogen by stimulating aromatase activity,[69] and a reduced androgen:estrogen ratio has been identified in both male and female RA patients.[70]

Abnormal Estrogen Levels

Unlike androgens, estrogens may be involved in sustaining the inflammatory activity of activated T cells[62] and humoral immunity.[71] Estradiol levels have been found to be higher in RA patients than controls and strongly and positively associated with indices of inflammation.[63] A large 5-year study comprising 689 patients with similar disease duration and severity found that gender is a major predictor of remission in early RA. Women have a lower androgen:estrogen ratio and, at 2 and 5 years, had more severe disease as well as 16% to 22% fewer remissions than men. This effect could not be explained by any other differences between the groups, including disease duration, age, and treatments used.[71]

DIAGNOSIS

The most commonly used criteria in the diagnosis of RA have been those issued by the American College of Rheumatology (ACR) in 1987; however, the sensitivity and specificity of these criteria are low, especially in early disease.[72] Because earlier diagnosis allows for earlier and more aggressive treatment, which may lead to better outcomes,[73] the ACR engaged in a joint initiative with the European League Against Rheumatism to create new guidelines that classify definite RA based upon the presence of synovitis in at least one joint, with no alternative explanation, and a score of 6 or greater in a four-tier rubric (see Table 205-1).[74]

Laboratory Findings

Rheumatoid Factor

RF is made up of a group of antibodies, usually IgM, that bind the Fc fragment of IgG. Although it is present in 70% to 80% of RA patients, a variety of conditions can cause elevations of RF, and 4% of apparently healthy individuals test positive as well.[2] Despite the relatively low sensitivity and specificity of the RF test, its presence is a confirmatory finding in the diagnosis of RA and seropositivity is associated with worse outcomes.[75]

TABLE 205-1 **Classification Criteria for Rheumatoid Arthritis**

Joint Involvement: Select the One with Highest Point Value	
1 medium-large joint	0 points
2-10 medium-large joints	1 point
1-3 small joints	2 points
4-10 small joints	3 points
10+ small joints	5 points
Serology	
Seronegative for RF and anti-CCP	0 points
Low-titer of RF and/or anti-CCP	2 points
High-titer of RF and/or anti-CCP (more than three times the upper limit of normal)	3 points
Duration of synovitis	
Less than 6 weeks	0 points
6+ weeks	1 point
Acute phase reactants	
Normal ESR and CRP	0 points
Elevated CRP or ESR	1 point

Data from Aletaha D, Neigi T, Silman A, et al. 2010 Rheumatoid arthritis classification criteria: An American college of pheumatology/European league against rheumatism collaborative initiative 62, no 9 (Sept 2010): 2569-81.

Anti–Cyclic Citrullinated Peptide Antibodies

Anti-CCP antibodies have emerged as a much more specific indicator of RA than RF as well as a better predictor of clinical course. Whereas the sensitivity of anti-CCP antibodies testing is similar to that of RF (70%-80%), its specificity is greater than 95%.[2] These autoantibodies, as well as RF, have been identified as much as 10 years prior to diagnosis,[76] and their presence heralds more aggressive disease and poorer prognosis.[1] No single laboratory test is definitive for the diagnosis of RA, and patients may be seropositive for anti-CCP, RF, both, or neither.

Erythrocyte Sedimentation Rate and C-Reactive Protein

The ESR and CRP are acute-phase reactants that become elevated during active inflammation. Although not specific to RA, they are useful in confirming the diagnosis and monitoring disease activity and response to treatment. Because RA patients are at increased risk for cardiovascular disease,[77] CRP in particular is a useful marker of cardiovascular risk as well.

Other Laboratory Abnormalities

Anemia, usually normocytic and normochromic or hypochromic, is quite common in RA and in chronic inflammatory diseases in general. Although the serum iron level and total iron-binding capacity are usually low, supplemental iron is of no value and may actually promote further damage due to free radicals. Because serum ferritin is an acute-phase reactant, iron stores may appear falsely elevated in RA when ESR and/or CRP are elevated.[78] Antinuclear antibodies may be present but at lower levels than in SLE.[2] Joint aspiration is not necessary to diagnose RA but may be necessary to rule out crystalline arthropathies or septic arthritis.

Other Diagnostic Testing

It is important to keep in mind that some other conditions can mimic RA and should be ruled out before a diagnosis is made. These include vitamin D deficiency, hemochromatosis, hypothyroidism, and infections such as Lyme disease and hepatitis B and C. Other tests to consider include the following:

- Hormone profiles: DHEA-S, testosterone, and estradiol
- Food allergies: see Chapter 15
- Lactulose-mannitol test: see Chapter 20
- Hydrogen-methane breath test: see Chapter 10
- Stool testing for digestive function and intestinal flora: see Chapter 27
- Urine testing: see Chapter 28
- Toxicity assessment: see Chapter 53

STANDARD MEDICAL THERAPY

Standard medical therapy is limited by its over reliance on pharmacologic therapies and focus on suppressing the disease process and its symptoms, most notably controlling the inflammation and free radicals that mediate joint damage[79] while failing to address the complex underlying causes of this disease. The effects and side effects of these drugs exacerbate many contributing factors to the disease process and possess significant morbidity and mortality risks of their own. Pharmacologic therapies generally fall into three categories: NSAIDs, disease modifying antirheumatic drugs (DMARDs), and biological therapies. Nonpharmacologic approaches include reduction of joint stress, physical and occupational therapy, and surgery.[2]

Nonsteroidal Antiinflammatory Drugs and Cyclooxygenase Inhibitors

Usually implemented before formal diagnosis,[1] NSAIDs are first-line antiinflammatory and analgesic medications that suppress symptoms while also accelerating factors that promote the disease process. NSAIDs can inhibit chondrocytes and cartilage formation[80] and promote chondrolysis and joint destruction.[81] Furthermore, they promote several factors thought to contribute to the pathogenesis of RA by increasing hyperpermeability of the GI tract,[82] dysbiosis,[83] free radicals in synovial fluid,[84] enteric inflammation, bacterial overgrowth, and bacterial translocation.[85] NSAIDs also cause serious GI side effects—including ulcers, hemorrhage and perforation—that led, according to one study, to 107,000 hospitalizations and 16,500 deaths in 1 year among arthritis patients alone.[86]

To mitigate this massive GI toxicity, NSAIDs are sometimes coadministered with acid-blocking medications. These drugs help alleviate the upper GI damage but do not protect from the ensuing iatrogenic hypochlorhydria, which is a causative factor in SIBO,[87] still another contributing factor to the pathogenesis of RA. Another way to protect the GI tract is to use selective cyclooxygenase-2 inhibitors. Although they have a much-improved GI safety profile compared with non-selective NSAIDs, they may not completely protect the lower GI tract from injury[88] and are associated with adverse cardiovascular events.[89] Because RA patients are already at increased risk for cardiovascular disease, these drugs may not be appropriate for general use in this population.[90] Finally, all drugs in this class also pose the risk of renal toxicity, and chronic use of high doses in arthritis patients increases the risk for renal failure.[91]

Corticosteroids

Corticosteroid medications are generally reserved for patients who do not respond to NSAID therapy. By blocking the inflammatory response, including the production and secretion of inflammatory mediators such as histamine, prostaglandins, and leukotrienes, they suppress not only inflammation but the normal immune response as well. These may be of great benefit in acute symptom management, but they become problematic with long-term use. Corticosteroids are associated with more frequent serious infections (those requiring hospitalization)[92] and increased mortality. Even small doses (up to 7.5 mg prednisone or equivalent) carry an increased risk for infection and death when used long-term. One study found the risk of mortality increased by 14% after 1 year and 49% after more than 10 years of use compared with the status of RA patients who had not been treated with low-dose corticosteroids.[93]

Common side effects of long-term corticosteroids at higher doses bring their use further into question because they exacerbate the manifestations of RA itself. Side effects include chondrotoxicity,[94] osteoporosis,[95] increased intestinal permeability,[96] and cardiovascular disease[97] as well as an increased risk of myocardial infarction. Furthermore, the risk of peptic ulcers and GI bleeding in patients already using NSAIDs is exacerbated by corticosteroids.[3] Insomnia is also a side effect, and patients with RA are more susceptible to insomnia than the general population.[98] In fact, one study concluded that the fatigue experienced by RA patients may be more due to sleep fragmentation than a constitutional symptom of the disease itself.[99] Finally, depression is a common side effect of prednisone and is also common among patients experiencing chronic pain from diseases such as RA. Patients with RA who experience depression have worse outcomes[100] than those who are not depressed, thus further contraindicating the use of corticosteroids.

Synthetic Disease-Modifying Antirheumatic Drugs

Once reserved for severe cases, disease-modifying antirheumatic drugs (DMARDs) are now used as first-line therapies according to conventional treatment guidelines. Methotrexate is the most common drug used, with the best balance of efficacy and toxicity.[101] Originally used as a chemotherapeutic agent, this agent exerts an immunosuppressive effect by decreasing white blood cell production. The more severe side effects of methotrexate include gastrointestinal ulceration, severe bone marrow suppression, frequent infections, elevated risk of cancer, and damage to the lungs, liver, and kidneys. Other drugs in this class—including hydroxychloroquine (Plaquenil), azathioprine, cyclophosphamide, and leflunomide—have similar, and sometimes more severe side effects. Many patients may not actually continue long-term therapy with any DMARD beyond the first few years owing to adverse effects or lack of efficacy. However, there is evidence that beginning a DMARD within the first 3 months of diagnosis is associated with a decreased risk of joint erosion. Therefore, patients presenting with a diagnosis of RA will most often be on DMARDs, individually or increasingly in combination, and perhaps additional drugs to manage their side effects.

Biological Disease-Modifying Antirheumatic Drugs

Newer biological agents include TNF-α antagonists such as infliximab, etanercept, and adalimumab. Other members of this class include tocilizumab, an interleukin inhibitor, and abatacept, a drug acting on T lymphocytes. According to a recent review article,[102] these medications are no more effective than methotrexate when used as monotherapy. However, in about 10 comparative trials analyzed, the combination of TNF-α antagonists with methotrexate was more effective than methotrexate alone, especially in initially severe RA. The investigators found no firm evidence that other drug combinations were more effective than these. Unfortunately, drug-free remission is still very rarely achieved and most patients experience higher disease activity upon discontinuation of therapy.[103]

Many patients will experience significant improvement within a few weeks. However, blocking TNF-α without addressing the conditions that created the imbalance leads to long-term consequences, such as sepsis and pneumonia and an increased risk of reactivating tuberculosis.[104] A potent inflammatory mediator, TNF-α is also a critical part of the host defense against certain pathogens. For all patients using TNF-α inhibitors, vigilance for hypersensitivities, anemias, infections, and malignancy is required. Another study also showed accelerated atherosclerotic activity.[105] Long-term follow-up studies do not exceed 2 years; however, the risk of severe adverse effects is likely higher with drug combinations.[105]

THERAPEUTIC CONSIDERATIONS

RA is a multifactorial condition that requires a comprehensive therapeutic approach addressing all the factors known to be involved in the inflammatory disease process. Foremost in this approach is the use of diet.

Diet

Population studies have demonstrated that RA is less common in societies that favor a more "primitive" diet and is found at higher rates in societies consuming the so-called Western diet.[106] A diet

of organic whole foods, rich in vegetables and fiber and low in sugar, meat, refined carbohydrates, saturated fat, and additives appears to offer some protection against the development of RA as well as promise in its treatment.[107-110]

Adverse Food Reactions

The elimination of reactive foods has been shown to offer significant benefit to some individuals with RA.[111-114] The most common triggers in one study included corn (56%), wheat (54%); bacon/pork (39%); oranges (39%); milk and oats (37%); rye (34%); egg, beef, and coffee (32%); malt (27%); cheese and grapefruit (24%); tomato (22%); peanuts and cane sugar (20%); butter, lamb, soy, and lemon (17%). Nineteen percent of participants who continued to avoid their reactive foods remained well without medications for follow-up periods of up to 5 years.[115] Dietary elimination and challenge is one method of identifying triggering foods, which can be different for each patient. Some studies that fail to show any benefit from dietary intervention provide the entire experimental group with the same "hypoallergenic" diet, not one customized to each participant's particular sensitivity or sensitivities. One such group of investigators concluded that, "our data are not inconsistent with the possibility that individualized dietary manipulations might be beneficial for select patients with rheumatic disease."[116]

Therapeutic Fasting

Patients with RA have historically benefited from fasting. Short-term fasts of 3 to 5 days' duration are recommended during acute flares so as to induce a substantial reduction of joint pain, swelling, morning stiffness, and other symptoms of RA.[117] It is an obvious method for eliminating reactive foods but has effects that extend beyond allergen avoidance. Fasting increases serum DHEA-S and decreases serum IL-6, CRP, ESR, and disease activity[118]; it also has a favorable effect on intestinal permeability.[119] Juice, broth, and water fasts of longer duration, up to 10 days, have been shown to be effective as well. Strict water fasting should be done only under direct medical supervision. (For a full discussion, see Chapter 37.)

Vegetarian Diet

One 13-month controlled study began with a 7- to 10-day fast before transitioning to a vegetarian diet.[120] The fast consisted of herbal teas, garlic, vegetable broth, a decoction of potatoes and parsley, and carrot, beet, and celery juices. The diet was followed by a systematic reintroduction of a single food item every 2 days with elimination of foods that aggravated RA symptoms. The treatment group showed significant improvements compared with controls, and these improvements were maintained at 1-year follow-up in those patients still maintaining the diet. This study supported the positive results noted in prior studies of short-term fasting followed by a vegetarian diet,[121-123] and the pooling of these data in a systematic review showed statistically and clinically significant beneficial long-term effects.[124] Beyond allergy elimination, vegetarian diets are also associated with higher fiber intake and improved gut flora,[37,38] including decreased antibodies to *Proteus mirabilis*,[125] less SIBO, and an improvement in RA symptomatology.[40] Other changes included increased potassium intake, which may lead to improved biosynthesis and the release of cortisol[126] as well as a favorable fatty acid profile and increased antioxidant intake.

The Mediterranean Diet

Patients with established RA in one study obtained a reduction in inflammatory activity, an increase in physical function and improved vitality in 12 weeks on a Mediterranean diet.[127] Rich in seasonally fresh plant-derived foods, the Mediterranean diet is similar to the vegetarian diet with the addition of fish and poultry, low to moderate red meat, dairy and red wine, and olive oil as the main source of lipids.[128] Different types of dietary fats can either alleviate or aggravate RA[129] by influencing eicosanoid metabolism. Both vegetarian and Mediterranean diets are inherently low in saturated fats and arachidonic acid, the precursor to the inflammatory series-2 prostaglandins and leukotrienes, and rich in gamma-linolenic acid (GLA) and α-linolenic acid (ALA), the precursors to antiinflammatory series-1 and series-3 prostaglandins. The consumption of cold-water fish such as mackerel, herring, sardines, and salmon, which are rich in eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), further promotes antiinflammatory eicosanoids. A population-based case-control study of women living in the Seattle area compared fish consumption in 324 cases of RA with 1245 control cases.[130] Consumption of broiled or baked fish was associated with a dose-dependent decreased risk of RA. This may explain some of the antiinflammatory effects of the Mediterranean diet, which includes fish but relatively little meat. By excluding meats, not only preformed, proinflammatory arachidonic acid is removed from the diet but also a potential food allergen: several studies have found that RA patients are commonly allergic to meats, especially beef and pork.[115,131,132] Furthermore, the inclusion of olive oil produces additional benefits in RA, including antioxidant and antiinflammatory effects, competitive inhibition of omega-6 fatty acids, pain reduction, reduced morning stiffness, and improved patient evaluation of global disease.[133] Additionally, these effects seem to be synergistic with fish oils.

Dietary Antioxidants

The continuous production of free radicals within arthritic joints promotes joint degeneration, exhausts antioxidant systems, and may cause the low antioxidant levels commonly seen in RA patients.[134] The importance of consuming a diet rich in fresh fruits and vegetables in the dietary treatment of RA cannot be overstated. These are the best sources of antioxidants such as vitamin C, beta-carotene, vitamin E, selenium, and bioflavonoids, all of which promote healthy joints by neutralizing inflammation and supporting collagen structures. Antioxidants work together synergistically, such as needing vitamin C to regenerate vitamin E, and this may explain why systematic reviews have not found single antioxidant supplements to be effective but have documented benefit for antioxidant-rich diets.[135] The antioxidant content of vegetarian and Mediterranean diets almost certainly contributes to their effectiveness in treating RA. (For more information, see Chapter 108.)

Nutritional Supplements

Gamma-Linolenic Acid

Evening primrose, black currant, and borage oils contain GLA, an omega-6 fatty acid that acts as a precursor to the antiinflammatory prostaglandins of the 1-series. Although one study showed that the long-term supplementation with GLA produced a paradoxical increase in tissue arachidonic acid levels while decreasing tissue levels of EPA,[136] GLA nevertheless appears to provide antiinflammatory support in RA. In one double-blind study, 37 patients with RA were given either GLA (1.4 g/day) or placebo for 24 weeks. GLA supplementation reduced the number of tender joints by 36%, the tender joint score by 45%, the swollen joint count by 28%, and the swollen joint score by 41%.[137] In contrast, no patients in the placebo group showed significant improvement

on any measure. The subjects in the study did, however, continue to take antiinflammatory drugs, which may have masked a change in arachidonic acid and EPA levels or acted synergistically with the GLA. In any case, two recent reviews[138,139] found statistically significant improvements in pain and global function for GLA from data pooled from three randomized controlled trials. Although the investigators emphasized the need for more trials, their conclusions in favor of GLA were even stronger than those for fish oil.

Omega-3 Fatty Acids

The richest sources of omega-3 oils are cold-water fish and flaxseed oil. The ALA in flaxseed oil must be enzymatically converted to EPA and DHA to exert an antiinflammatory effect. Although several studies have shown that flaxseed oil is not as effective as fish oil, these studies failed to address zinc (a cofactor for delta-6-desaturase), and omega-6 fatty acids.[140,141] A study incorporating a low-omega-6 diet while supplementing with 13 g (approximately 1 tbsp) of flaxseed oil a day found that such supplementation, along with the restriction of linoleic acid and addressing underlying zinc deficiency, raises tissue EPA levels to an extent comparable with the effects of fish oil supplementation.[142] Several human and animal studies have demonstrated that flaxseed oil supplementation can inhibit the autoimmune reaction as well as fish oil.[143]

Supplementing with fish oils bypasses the metabolism of α-linolenic acid by directly supplying preformed EPA and DHA. Many published studies have documented the efficacy of fish oil.[144-149] Because it competitively inhibits COX-2, which is overexpressed in the RA synovium, supplementation has been shown in randomized trials to decrease long-term use of NSAIDs.[150] A recent review that included three meta-analyses of fish oil concluded that there is convincing evidence of benefit in RA, including briefer morning stiffness, fewer tender or swollen joints, less joint pain, less fatigue, and reduced serum markers of inflammation, such as CRP, IL-1β, TNF-α and LTB_4.[151] Supplements may have to be consumed for at least 12 weeks at a minimum daily dose of 3 g of combined EPA and DHA before effects become apparent.[152] Furthermore, fish oil may further benefit RA patients by decreasing cardiovascular risk. It is important to select a product that has been rigorously tested for contaminants such as heavy metals, polychlorinated biphenyls, dioxins, and lipid peroxides, or one may rely on cold-water fish and flaxseed oil for the omega-3 oils rather than fish oil capsules to help avoid these toxins.[153-155] (For more information about fish oils, see Chapter 91.)

Multivitamin/Multimineral Supplementation

Blood and/or tissue samples from RA patients indicate that such patients are deficient in many nutrients, including magnesium, folate, vitamin B_{12},[156] vitamin B_6,[157] zinc,[158] and selenium.[159,160] Many factors may contribute to this, including decreased dietary nutrient intake among RA patients,[161] decreased absorption due to impaired gut function, increased utilization of antioxidant nutrients due to elevated oxidative stress, and increased excretion of nutrients due to stress and medications. Studies are few in number and have produced conflicting results, and systematic reviews have failed to demonstrate benefit from supplementation of individual nutrients, but it is almost certainly the case that a multifactorial condition such as RA requires a multifaceted approach to treatment rather than a nutrient monotherapy. It appears reasonable, safe, and—at least hypothetically—efficacious to address deficiencies of multiple nutrients simultaneously. Following are specific nutrients to consider that have been found to be deficient and/or beneficial in some clinical trials with RA.

Selenium and Vitamin E

An important mineral cofactor for glutathione peroxidase and thioredoxin reductase, selenium is especially important for reducing the production of inflammatory prostaglandins and leukotrienes and controlling tissue damage due to free radicals. Clinical studies have not demonstrated improvement from selenium supplementation in RA; however, one clinical study did indicate that selenium combined with vitamin E had a positive effect.[162] In another randomized controlled trial, patients already diagnosed with RA who received 600 mg vitamin E twice a day showed significant pain reduction but no changes in clinical and biochemical indices of inflammation.[163] However, a review of five studies found no conclusive evidence of benefit from vitamin E or selenium supplementation alone.[164]

Zinc

A cofactor for delta-6-desaturase, the rate-limiting enzyme in omega-3 fatty acid metabolism, zinc deficiency is associated with poor conversion of ALA from flaxseed oil to EPA and DHA. Deficiency is common in RA patients, which may predispose them to increased inflammation due to impaired eicosanoid metabolism. Plasma zinc levels are inversely correlated with ESR, CRP, IL-1β, and TNF-α.[165] Zinc also has antioxidant effects and is a cofactor to the enzyme superoxide dismutase (copper-zinc SOD). Patients using corticosteroids may be at increased risk for zinc deficiency because these medications have been shown to decrease plasma zinc and increase urinary zinc.[166] Several studies have demonstrated a slight therapeutic effect from zinc supplementation in RA patients.[167-169]

Manganese and Superoxide Dismutase

Manganese functions in a different form of the antioxidant enzyme superoxide dismutase (manganese SOD). Manganese-containing SOD is deficient in patients with RA.[170] The injectable form of this enzyme has been shown to be effective in the treatment of RA[171]; however, it has not been demonstrated that oral supplementation affects SOD levels in tissue.[172] What has been established is that oral manganese supplementation increases SOD activity.[173] Although no clinical studies have been conducted to determine the effectiveness of manganese in the treatment of RA, it appears to be indicated on the basis of the low levels seen in patients with RA as well as its biochemical functions.

Vitamin C

An important antioxidant, vitamin C concentrations in white blood cells and plasma are significantly decreased in patients with RA.[174] Supplementation with vitamin C increases SOD activity, reduces histamine levels, and provides antiinflammatory action.[175,176] One intervention study with a Mediterranean diet showed a negative correlation between plasma vitamin C levels and RA disease activity[177]; this was corroborated by another study that found an inverse correlation between vitamin C levels and CRP.[178]

Pantothenic Acid

Whole-blood levels of pantothenic acid have been reported to be lower in patients with RA than in normal controls and inversely correlated with disease activity.[179] Correction of these low levels brings about some alleviation of RA symptoms. In one

double-blind study, a subjective improvement of RA symptoms was noted in patients receiving 2 g/day of calcium pantothenate.[180] Patients noted improvements in duration of morning stiffness, degree of disability, and severity of pain.

Pyridoxine (Vitamin B_6)

There is a clear relationship between low serum levels of pyridoxal 5'-phosphate and inflammatory indicators of RA. One cross-sectional study found that vitamin B_6 levels in plasma were lower in patients with high ESR and CRP levels, who also had more disability, pain, fatigue, and swollen joints.[181] This circumstance was not attributed to deficiency of intake but rather to ongoing chronic inflammatory processes. In a separate study,[182] higher levels of homocysteine were also noted and correlated with low vitamin B_6 status in RA patients, consistent with the increased risk of cardiovascular disease seen in these patients.

Copper

The wearing of copper bracelets has been a long-time folk remedy that appears to have some scientific support, as described in a double-blind study performed in Australia. Presumably copper is absorbed through the skin and is chelated to another compound that can exert antiinflammatory action.[183] Copper salicylate is a form of aspirin that yields better results in reducing pain and inflammation than standard aspirin preparations in patients with RA.[184,185]

Copper is also used in copper-zinc SOD. Deficiency may result in significant susceptibility to free radical damage as a result of decreased SOD levels. However, an excess intake of copper may be detrimental because of its ability to combine with peroxides and damage joint tissues.[186]

Vitamin D

Vitamin D is a steroid hormone that displays immunoregulatory and antiinflammatory properties. Epidemiologic evidence indicates a significant association between vitamin D deficiency and an increased incidence of several autoimmune diseases, including RA.[187] One study identified lower vitamin D levels and a higher incidence of RA in northern European countries compared with southern European countries. In both parts of Europe, however, low 25(OH)D3 levels were significantly correlated with worse RA symptomatology.[188] Furthermore, a high intake of vitamin D is associated with a decreased risk of RA.[189]

Vitamin D also plays an important role in normal calcium metabolism. One study involving 147 women, mean age of 50.9 years, found that 13% had vitamin D levels below the threshold for vitamin D–deficiency osteomalacia.[190] In the winter, 73% had serum concentrations below the normal range. The authors suggest that there is a disturbance in vitamin D metabolism in RA that might play a role in RA-associated osteoporosis.

Pancreatic Enzymes and Hydrochloric Acid

Impaired digestion from inadequate secretion of pancreatic enzymes and/or hydrochloric acid, which is common in RA patients, can be a major contributor to the disease process.[191,192] In addition to poor assimilation of ingested nutrients, incompletely digested food molecules can be inappropriately absorbed, stimulating an immune response. In one study, 80% of untreated RA patients had reduced maximal gastric acid output.[193] Gastric acid also plays a role in passive immunity, and hypochlorhydric or achlorhydric patients may be predisposed to SIBO. Half of RA patients in one study who had inadequate hydrochloric acid secretion also had SIBO, and restoration of gastric pH can help to resolve the overgrowth.[39]

Beyond their physiologic role in digestion, pancreatic enzymes may offer additional benefits when taken between meals. Specifically, the proteases in pancreatin have been shown to reduce circulating levels of immune complexes in RA and other autoimmune diseases.[194,195] Because clinical improvements usually correspond with decreases in levels of immune complexes, proteolytic enzyme supplementation is often warranted. (For more information, see Chapter 111.)

Probiotics

Probiotic supplementation is immunomodulatory. Commensal organisms interact with Toll-like receptors in the intestinal mucosa to promote immune tolerance and regulatory T-cell formation while blocking NF-kappaB, inflammation, and allergies. These effects in RA patients may be strain-specific.[196] One small-scale human trial on *Lactobacillus rhamnosus* GG did not show a clinical benefit,[197] however, a recent study on *Bacillus coagulans* GBI-30, 6080, produced statistically significant improvement in pain scale compared with placebo. Treatment also resulted in greater improvement in patient global assessment, self-assessed disability, CRP, ability to walk 2 miles and participation in daily activities.[198] Probiotics, prebiotics, and/or antimicrobial compounds may be indicated in cases of dysbiosis and SIBO in addition to dietary modification. (For more information, see Chapters 115 and 116.)

Botanical Medicines

Many botanicals possess significant antiinflammatory action and are useful in the treatment of RA. The suggestions made here represent some of the more popular and better researched of these botanical medicines.

Curcuma longa

Curcumin, the yellow pigment of *Curcuma longa* (turmeric), exerts excellent antiinflammatory and antioxidant effects[199-204] and has been found to be as effective as cortisone or phenylbutazone in models of acute inflammation. Molecular targets include transcription factors (e.g., NF-kappaB, PPAR-gamma), enzymes (e.g., COX-2, 5-LOX), and cytokines (e.g., TNF-α, IL-1, IL-6).[205] Animals models also indicate that curcumin may enhance endogenous corticosteroid activity, perhaps through increased synthesis and/or release, potentiation of receptor sites, or slowing of catabolic pathways.

One double-blind clinical trial compared curcumin (1200 mg/day) with phenylbutazone (300 mg/day) in RA patients.[206] The improvements in the duration of morning stiffness, walking time, and joint swelling were comparable in both groups. Furthermore, although phenylbutazone is associated with significant adverse effects, curcumin has not been shown to produce any side effects. It is noteworthy that curcumin also lacks any direct analgesic action.

One concern regarding curcumin has been absorption. There now exist a number of methods and products that enhance the absorption. One of the first methods was using piperine, a compound found in black pepper.[207] A more recent method is complexing the curcumin with soy phospholipids to produce the product Meriva.[208] Absorption studies in animals indicate that peak plasma levels of curcumin after administration of Meriva were fivefold higher than those after administration of regular curcumin. Studies with another advanced form of curcumin, Theracurmin, shows even greater absorption (e.g., 27 times greater than regular curcumin).[209]

Bromelain

Bromelain is a mixture of enzymes found in pineapple. Since 1957, more than 200 scientific papers have appeared in the research literature documenting a wide variety of beneficial effects,[210] including reduced inflammation in RA.[211] Much of its effects are due to activation of compounds that break down the inflammation-induced fibrin matrix that leads to inadequate tissue drainage and edema. Bromelain also blocks the production of kinins, compounds produced during inflammation that increase swelling and cause pain. A proteolytic enzyme product containing bromelain, papain (an enzyme from papaya), trypsin, and chymotrypsin (pancreatic enzymes) was shown to decrease excessive levels of transforming growth factor beta in human blood,[212] and polymorphisms of this transforming growth factor have been linked with the progression of joint destruction in rheumatoid arthritis.[213]

Zingiber officinalis

Ginger *(Z. officinalis)* contains antioxidants and exerts antiinflammatory effects by inhibiting the synthesis of prostaglandins, thromboxanes, and leukotrienes. A preliminary clinical study was conducted with seven RA patients in whom conventional drugs had provided only temporary or partial relief.[214] All patients were treated with ginger. One patient took 50 g/day of lightly cooked ginger and the other six took either 5 g/day of fresh ginger or 0.1 to 1 g/day of powdered ginger. Despite the difference in dose, all patients reported a substantial improvement, including pain relief, better joint mobility, and a decrease in swelling and morning stiffness.

In the follow-up to this study, 28 patients with RA (18 with osteoarthritis and 10 with muscular discomfort) who had been taking 500 to 4000 mg of powdered ginger for periods ranging from 3 months to 2.5 years were evaluated.[215] On the basis of clinical observations, it was reported that 75% of the patients with arthritis and 100% of those with muscular discomfort experienced relief in pain or swelling and that the effects were dose dependent.

Fresh ginger contains higher levels of gingerols as well as a protease that may act on inflammation much like bromelain and therefore may be more effective in the treatment of RA than dried preparations.[216] Most studies have used 1 g of dry powdered ginger root, which is a relatively small dose compared with the daily average of 8 to 10 g consumed in India. A daily dose of 2 to 4 g of dry powdered ginger is safe and may be effective in RA. This is roughly equivalent to 20 g of fresh ginger root, or a 0.5-inch slice. These amounts of ginger can easily be incorporated into the diet in fresh fruit and vegetable juices.

Tripterygium wilfordii Hook F

In Chinese medicine, *Tripterygium wilfordii Hook F* or thunder god vine, has a long history of use in RA and other autoimmune diseases. Although studies have focused almost exclusively on the root, both the folium and the radix of the plant appear to have antiinflammatory, analgesic, and immunosuppressive effects that may be effective in treating RA.[217] In a double-blind placebo-controlled study involving patients with long-standing RA in whom conventional therapy had failed, 80% of those who received a high dose (380 mg/day) of ethanol/ethyl acetate root extract had a positive response, defined as at least 20% improvement according to the American College of Rheumatology criteria. Forty percent of the low-dose (180 mg/day) group also responded positively, compared with none in the placebo group.[218] Another recent randomized, controlled trial demonstrated that 180 mg/day of *Tripterygium* extract was more effective than sulfasalazine 1 g twice a day.[219] Two other review articles have documented the efficacy of this herb in the treatment of RA.[220,221]

Side effects reported for this herb include GI upset, diarrhea, headache, hair loss, menstrual abnormalities, and hypertension. Randomized controlled trials have demonstrated efficacy and decreased advere reactions from sustained-release table,[222] topical applications,[223] and coadministration with *Glycyrrhiza glabra* (licorice) root.[224] Coadministration of *Tripterygium* with methotrexate may improve efficacy and decrease side effects compared with methotrexate alone.[225]

Valeriana officinalis

Between 54% and 70% of RA patients report sleep disruptions. *V. officinalis*, or valerian, has long been used as a sleep aid and has been shown to decrease the time between going to bed and the first cycle of deep sleep compared with placebo in RA patients.[226] Valerian is a sedative and anxiolytic that sensitizes GABA receptors and may also affect the actions of serotonin and adenosine. Even if they were unaware of it, one study found that all RA patients had marked sleep disturbances; it was therefore concluded that the fatigue experienced commonly in RA might be a sign of undiagnosed sleep disturbance rather than a product of the disease process itself.[99] This fatigue is frequently perceived by RA patients as overwhelming, uncontrollable, and ignored by their doctors.[227] Addressing an underlying sleep disorder may provide profound relief on many levels.

Another study found that the morning symptoms of RA were correlated with a nonrestorative sleep disorder.[228] Inadequate sleep can lead to inflammation, as measured by increased CRP,[229] and both CRP and sleep problems are inversely related to pain thresholds in RA patients.[230] Therefore, using valerian to improve the quality of sleep may also improve fatigue, pain threshold, and psychological measures of quality of life.

Physical Medicine

Exercises

Exercise can improve strength and performance while maintaining range of motion in RA patients. Furthermore, it decreases cardiovascular risk, RA disease activity, and systemic inflammation as evidenced by reduced ESR.[231] Patients with well-developed disease should begin with progressive, passive range-of-motion and isometric exercises, gradually introducing active range-of-motion and isotonic exercises as appropriate. One randomized controlled multicenter trial studied the effects of high-intensity exercise in over 300 patients with RA. Participants were given either standard physical therapy or a high-intensity exercise program for 2 years. Whereas radiographic damage of the large joints was not increased except possibly in those patients who had considerable baseline damage, high-intensity exercise improved functionality and mood and provided a sense of well-being.[232]

Hydrotherapy

Heat is typically used to help relieve stiffness and pain, relax muscles, and increase range of motion. Moist heat (e.g., moist packs, hot baths) is more effective than dry heat (e.g., heating pad); paraffin baths are used if skin irritation from regular water immersion develops. Cold packs are of value during acute inflammatory flare-ups or following hot applications.

Constitutional hydrotherapy is a classic naturopathic technique utilizing alternating hot and cold applications to the torso and back in combination with electrical stimulation. As with contrast hydrotherapy in other parts of the body, this creates an alternating vasodilation and vasoconstriction—a sort of vascular pump—intended to improve the circulation of blood through the viscera, promote detoxification, and tone the nervous system. Rather than treating the symptomatic joints, this therapy is focused on the causative factors underlying the disease: healing impaired gut function and eliminating metabolic wastes and xenobiotic toxins.

Psychological Aspects

Optimistic patients with RA report better psychosocial and physical functioning than pessimistic patients, who adopt passive coping strategies like staying in bed for many hours a day.[233] Patients who believe they have the ability to control and decrease pain by using spiritual/religious coping methods tend to have less joint pain and negative moods and are much more likely to have higher levels of general social support. Positive support from a spouse[234] or other family member is inversely related to depression and can significantly enhance quality of life. Patients who lack support or experience other challenges—including histories of abuse, somatization disorders, and obsessive-compulsive disorders—often rely on their health care providers for these needs. Rheumatic patients want to be seen as individuals and not as mere diagnoses, to be believed as far as pain and suffering are concerned, and to have their subjective experience acknowledged.[235] A supportive and validating doctor–patient relationship is vital in diseases like RA. Counseling is often appropriate to explore common themes experienced by RA patients, such as coping with severe pain, self-esteem issues, negative feelings, reflections on the past, concentration on recovery from disease, support, and others.[236]

THERAPEUTIC APPROACH

RA is often an aggressive disease that requires aggressive treatment. In mild to moderate RA, the measures below are extremely effective. Foremost is the use of diet to reduce the causes and ameliorate the symptoms of RA. Symptom relief can also be attained through the use of physical medicine techniques, botanicals, and nutrients. In severe cases, NSAIDs and other drugs may be necessary, at least in the acute phase. However, the physician should encourage patients not to abandon natural measures, because they will actually enhance the effectiveness of the drugs, allowing for lower doses when drugs are necessary while providing a foundation for healing by addressing the underlying causative factors and using modalities that are both safe and beneficial in long-term use.

Diet

The first step is a therapeutic fast or elimination diet, followed by careful reintroduction of individual foods to detect those that trigger symptoms. Although any food can cause a reaction, the most common are wheat, corn, dairy products, beef, nightshade family foods (tomato, potato, eggplant, peppers), pork, citrus, oats, rye, egg, coffee, peanuts, cane sugar, lamb, and soy.

After all allergens have been isolated and eliminated, a vegetarian or Mediterranean-style diet rich in organic whole foods, vegetables, cold-water fish (mackerel, herring, sardines, and salmon), olive oil, and berries and low in sugar, meat, refined carbohydrates, and animal fats is indicated.

Supplements

- High-potency multiple-vitamin-and-mineral formula, as described in Chapter 6, Supplementary Measures
- Fish oils: 3000 mg EPA+DHA a day
- Vitamin C: 500 to 1000 mg/day
- Selenium: 200 to 400 mcg/day
- Vitamin E (mixed tocopherols): 200 to 400 IU/day
- Vitamin D_3: 2000 to 4000 IU/day
- Choose one of the following:
 - Grape seed extract (>95% procyanidolic oligomers): 100 to 300 mg/day
 - Pine bark extract (>95% procyanidolic oligomers): 100 to 300 mg/day
 - Or, some other flavonoid-rich extract with a similar flavonoid content, "super greens formula" or other plant based antioxidant that can provide an oxygen radical absorption capacity (ORAC) of 3000 to 6000 units or higher per day
- Probiotic *(Lactobacillus* and *Bifidobacter sp.):* minimum of 5 to 10 billion colony forming units daily
- Pancreatin (10× USP): 350 to 750 mg between meals three times daily; or Bromelain: 250 to 750 mg (1800 to 2000 MCU) between meals three times a day

Botanical Medicines

The following botanicals may be used alone or in combination with others. Severe inflammation and joint destruction require more aggressive therapy.

- Curcumin: Choose one of the following:
 - Curcumin: 400 mg three times a day between meals
 - Meriva: 1000 to 2000 mg/day
 - Theracurmin: 600-1200mg/day
- Ginger: 8 to 10 g of dried ginger or ginger extracts standardized to contain 20% gingerol and shogaol at a dosage of 100 to 200 mg three times a day
- *Tripterygium wilfordii Hook F*: 360 to 570 mg/day of ethyl acetate extract
- *Valeriana officinalis*: 1.5 to 3 g/day of dried herb

Physical Medicine

- Heat (moist packs, hot baths, etc.): 20 to 30 minutes, one to three times daily
- Cold packs for acute flareups or following heat
- Active or passive range-of-motion exercises: 3 to 10 repetitions once or twice a day
- Progressive isometric (and isotonic as the joints improve) exercise: 3 to 10 repetitions several times a day with generous periods of rest

Counseling/Psychological Therapy

A supportive and validating doctor–patient relationship should be established. Priorities include stress management and evaluation for depression and of the patient's support network. Attempts should be made to work with spouses and family members if possible.

OTHER CONSIDERATIONS

Positive results from other testing may indicate DHEA, testosterone, vitamin D, and therapeutics for intestinal permeability, SIBO, dysbiosis, and environmental toxicity.

DIAGNOSTIC SUMMARY

- Chronic acneiform eruption on the face of middle-aged and older adults associated with facial flushing and telangiectasia.
- The acneiform component is characterized by papules, pustules, and seborrhea; the vascular component by erythema and telangiectasia; and the glandular component by hyperplasia of the soft tissue of the nose (rhinophyma).
- The primary involvement occurs over the flush areas of the cheeks and nose.
- More common in women (3:1) but more severe in men.

GENERAL CONSIDERATIONS

Rosacea is a common, chronic, progressive inflammatory skin disorder in which the nose and cheeks are abnormally red and may be covered with pimples similar to those seen in acne (see Chapter 141). Rosacea was originally called "acne rosacea" because its inflammatory papules and pustules so closely mimic those of acne vulgaris. Unlike acne vulgaris, whose etiology is based on the interaction of abnormal keratinization, increased sebum production, and bacterially induced inflammation, rosacea's inflammation is vascular in nature. Rosacea generally occurs in patients between the ages of 25 and 70 years, and it is much more common in people with fair complexions. Women are three times more likely than men to have rosacea, although the disease is generally more severe in men. At least 13 million Americans are known to be affected.[1,2]

Rosacea is divided into three stages, but because progression does not necessarily occur, rosacea is also often divided into four specific subtypes (erythematous telangiectatic, papulopustular, phymatous, and ocular)[1,3,4]:

- *Stage I:* In this stage, or erythematous telangiectatic rosacea, erythema triggered by hot beverages, spicy foods, and alcohol may persist for hours; telangiectasias are noticeable on the central third of the face; and burning, stinging, and itching after the application of cosmetics, fragrances, and sunscreens become a major complaint.
- *Stage II:* In this stage, or papulopustular rosacea, the hallmarks are inflammatory papules and pustules. Flushing, telangiectasias, and seborrhea increase, and minimal enlargement of facial pores becomes obvious.
- *Stage III:* A small number of patients progress to this stage, or phymatous rosacea, which exhibits deep inflammatory nodules, large telangiectatic vessels, markedly dilated facial pores, sebaceous gland hyperplasia, and tissue hyperplasia, especially of the nose (rhinophyma).

Ocular rosacea describes the spectrum of eye findings associated with the skin involvement. Ocular rosacea can cause the eyes to have a watery or bloodshot appearance, the sensation of a foreign body, burning or stinging, dryness, itching, light sensitivity, and a host of other signs and symptoms. Sties are a common sign of rosacea-related ocular disease, and some individuals may have decreased visual acuity owing to corneal complications.

It is important to point out that what differentiates the flushing that rosacea patients experience is its prolonged nature and intensity. Many people without rosacea experience evanescent flushing in response to embarrassment, exercise, or hot environments. However, although evanescent flushing episodes last from several seconds to few minutes, the flushing that the typical rosacea patient describes lasts longer than 10 minutes and is more red than pink, with an accompanying burning or stinging sensation.

The stimuli that bring on such flushing in rosacea patients may be acutely felt emotional stress, hot drinks, alcohol, spicy foods, exercise, cold or hot weather, or hot baths or showers. However, many times the episodes are without known stimuli.

Etiology

The cause of rosacea is poorly understood, although numerous theories have been offered. Included in the factors that have been suspected of causing acne rosacea are the following:

- The mite *Demodex folliculorum*
- Alcoholism
- Menopausal flushing
- Vasomotor neurosis
- Seborrheic diathesis
- Local infection
- Food allergies
- B-vitamin deficiencies
- Gastrointestinal disorders

Most cases of rosacea are associated with moderate to severe seborrhea, although sebum production is not increased in many. Vasomotor lability is prevalent, and migraine headaches are three times more common in persons with rosacea than in age- and gender-matched controls.

There is also emerging evidence for a role for *Helicobacter pylori* in rosacea (discussed below as well). It is known that *H. pylori* infection increases several vasoactive substances, such as histamines, prostaglandins, and leukotrienes, and various cytokines. However, these vascular mediators are found only with *H. pylori* strains that also produce a specific cytotoxin, cytotoxin-associated gene A (CagA). The presence of *H. pylori* capable of producing this cytotoxin may be more important in the etiology of rosacea than other strains. When the presence of CagA was assessed in 60 rosacea patients and compared with age- and gender-matched control subjects with nonulcer dyspepsia, researchers found that when infected with *H. pylori,* 67% of rosacea patients versus only 32% of controls had positive findings for CagA. In addition, these patients had elevated systemic levels of tumor necrosis factor-α and interleukin 8. After the eradication of *H. pylori* infection in the rosacea patients, symptoms disappeared in almost all of them (51 of 53) and tumor necrosis factor-α and interleukin 8 levels normalized.[7,8]

In regard to the etiology of rosacea, the bottom line is that because many of the implicated triggers of rosacea are experienced by healthy persons who never go on to develop the symptoms or signs of rosacea, it is believed that rosacea-prone individuals must have an inherent sensitivity to these triggers.

THERAPEUTIC CONSIDERATIONS

One of the first recommendations to the patient with rosacea is to avoid those stimuli that tend to exacerbate the disease—exposure to extremes of heat and cold, excessive sunlight, and ingestion of hot liquids, alcohol, and spicy foods. The conventional medical treatment of rosacea is usually oral tetracycline, especially for the papular or pustular lesions, although this treatment usually only controls rather than eradicates the disease. Topical therapy for rosacea with antibiotics or synthetic retinoids is generally less successful than systemic antibiotic treatment. Also, although topical corticosteroids may initially improve signs and symptoms, long-term corticosteroid therapy is not advisable because it may actually lead to rosacea. The treatment of chronic skin changes and severe rhinophyma may require laser treatments and surgical intervention respectively.

The natural approach to rosacea is to try to identify and eliminate contributing factors if possible. Key factors to address are hypochlorhydria, eradication of *H. pylori,* elimination of food allergies, and optimal intake of B vitamins.

Hypochlorhydria

Gastric analysis of patients with rosacea has led to the postulate that it is the result of hypochlorhydria.[1] Psychological factors—such as worry, depression, and stress—often reduce gastric acidity.[2] Hydrochloric acid supplementation results in marked improvement in those patients with rosacea who have achlorhydria or hypochlorhydria.[6,7] Patients with rosacea have also been shown to have diminished secretion of lipase (although bicarbonate and chymotrypsin secretion were normal) and to benefit from pancreatic supplementation.[8]

Helicobacter pylori

Given the high incidence of hypochlorhydria, it is perhaps not surprising that a high incidence of *H. pylori* infection in the stomach has also been found in patients with rosacea.[9] In a pilot study, *H. pylori* was found in 46 of 94 patients with rosacea, 38 of 88 patients with other inflammatory diseases, and 5 of 14 patients without an inflammatory disease. The researchers believed that the flushing reaction in rosacea is caused by gastrin or vasoactive intestinal peptides. They also quoted an Irish study that found that 19 of 20 patients with acne rosacea tested positive for *H. pylori.*

Another study that evaluated histologic sections of the stomach mucosa found that 84% of 31 patients were *H. pylori*–positive.[10] Interestingly, 20% of the patients who tested histologically positive also tested serologically negative for the organism. The consistency between clinical success in the treatment of rosacea with metronidazole and the abatement of *H. pylori* isolates and serologic results after treatment provides additional evidence suggesting an etiologic relationship between rosacea and *H. pylori* infection. However, it is also possible that *H. pylori* is simply associated with rosacea and is not a causative factor per se, because patients with rosacea may have rates of *H. pylori* infection similar to those in healthy subjects.[11] Interestingly, patients with rosacea complain significantly more frequently of "indigestion" and use more antacids than the general population.[11]

A large number of studies have now confirmed a strong association between *H. pylori* and rosacea, with a 2003 study showing a correlation between the severity of rosacea and the level of infection.[12]

Food Allergy

The statistically significant incidence of indigestion and migraine headaches accompanying rosacea points to food intolerance, as does the reflex flushing caused by vasodilating substances. Some of the later studies seem to support the concept of rosacea as a hypersensitivity disorder. Although these studies have focused on local factors, it is possible that given the known association of rosacea with dietary factors exacerbating the skin flushing, food hypersensitivity plays a significant role.

B Vitamins

The administration of large doses of B vitamins has been shown to be quite effective,[13] with riboflavin appearing to be the key factor. For example, researchers on B vitamins were able to infect the skin

of riboflavin-deficient rats with the mite *Demodex folliculorum* but not the skin of normal rats.[14] This mite was once considered a causative factor in rosacea and may still be a factor in some patients, especially those with more granulomatous lesions. Evidence suggests that a delayed hypersensitivity reaction in follicles is triggered by *D. folliculorum* antigens, stimulating the progression of the affection to the papulopustular stage.[15]

Although B vitamins are important for patients with rosacea, care must be exercised because some patients' rosacea may be aggravated by large doses of these common nutrients. There is a case report of a 53-year-old woman who presented to a dermatology clinic with a 9-month history of a facial eruption resembling acne rosacea. Treatment with oral hydroxychloroquine, ibuprofen, terfenadine, prednisone, erythromycin, and tetracycline had been tried during the 9 months without success. Topical desoximetasone, hydrocortisone, and cosmetic elimination also yielded no benefit. A patch test showed a positive reaction to nickel. The eruption began at the time of a personal stress as the patient was going through a marital separation. To help with her stress, the patient began taking 100 mg/day of pyridoxine and 100 mg/day of vitamin B_{12}. Discontinuation of the vitamins resulted in a dramatic improvement; with rechallenge, the condition reappeared. The investigators noted that inflammation and exacerbations of acne related to vitamins B_2, B_6, and B_{12} have been reported in the European literature.[16]

Zinc

Zinc supplementation has been shown to be helpful in acne vulgaris and may also be effective in acne rosacea. To test this hypothesis, 25 patients with rosacea were evaluated and given a clinical score, then randomly allocated to receive either zinc (23 mg from zinc sulfate) or identical placebo capsules three times daily. After 3 months, the patients crossed over. A total of 19 patients completed the study. In the group started on zinc, the scores before therapy ranged from 5 to 11. The mean started to decrease directly after the first month of therapy with zinc sulfate to a significantly lower level. After shifting to placebo treatment, the mean started to rise gradually in the fifth month but remained significantly lower than the levels before therapy. In the group started on placebo, the score before therapy ranged from 5 to 9. The mean remained high in the first 3 months of therapy while the patients were on placebo. After shifting to zinc sulfate, the mean started to decrease after the fourth month to significantly low levels. No important side effects were reported apart from mild gastric upset in 3 (12%) patients on zinc sulfate. The authors concluded that zinc is a good option in the treatment of rosacea because it was found to be safe and effective and had no significant side effects.[17]

Topical Azelaic Acid

Topical application of azelaic acid (AzA) appears to be extremely effective in papulopustular rosacea. Initially, AzA was released in a 20% cream formulation and was shown in this vehicle to be effective in the treatment of mild to moderate rosacea. A 15% gel formulation of AzA vastly improved the delivery of AzA and has been proved to be superior in head-to-head studies to the 20% AzA cream. It is and equally as effective as metronidazole cream or gel.[18-20] In a meta-analysis of five double-blind trials involving topical azelaic acid (cream or gel) for the treatment of rosacea compared with placebo or other topical treatments, four of five studies demonstrated significant decreases in mean inflammatory lesion count and erythema severity after treatment with AzA compared with placebo, and AzA was found to be equal to metronidazole in papulopustular rosacea. However, no significant decrease in the severity of telangiectasia occurred in any treatment group.[19]

THERAPEUTIC APPROACH

Although the causes of rosacea have not yet been determined, sufficient information is available to treat most affected patients adequately. Eradication of *H. pylori* infection (when present) and control of hypochlorhydria and food intolerance form the basis of therapy. This approach is supported with supplementation of B-complex vitamins and the avoidance of vasodilating foods.

General Recommendations

See Chapter 141 for general recommendations for acne.

Diet

The patient should avoid coffee, alcohol, hot beverages, spicy foods, and any other food or drink that causes a flush. Also to be eliminated from the diet are all refined and/or concentrated sugars, foods containing *trans* fatty acids such as milk, milk products, margarine, shortening and other synthetically hydrogenated vegetable oils, as well as fried foods and foods high in iodized salt.

Supplements

- Vitamin B complex: 100 mg/day (avoid niacin)
- Pancreatin (8-10× USP): 350 to 500 mg before meals
- Hydrochloric acid: follow guide provided in Appendix 7
- Zinc: 60 to 75 mg/day for no more than 3 months, followed by 15 to 20 mg/day thereafter
- Topical zinc: application of 15% azelaic acid gel

DIAGNOSTIC SUMMARY

- Branny or greasy scaling over erythematous skin patterned on the sebum-rich areas of the scalp, face, and trunk. Facial areas include the forehead, eyebrows, eyelashes, nasolabial folds, and beard. Truncal involvement includes the presternal region, umbilicus, axillae, inframammary and inguinal folds, and perineum.
- The scalp appearance varies from mild, patchy dandruff to widespread, thick, adherent crusts; it may involve the anterior and posterior hairline and the periauricular skin. In infants it occurs as "cradle cap."
- Usually nonpruritic, although active phases can manifest with burning and itching.
- Seasonal; worse in winter.

GENERAL CONSIDERATIONS

Seborrheic dermatitis is a common papulosquamous condition similar in appearance to psoriasis. Clinically it may be associated with excessive oiliness (seborrhea) and dandruff. The scale may be yellowish and either dry or greasy. The erythematous, follicular, scaly papules may coalesce to form large plaques or circinate patches. Flexural involvement is often complicated by candidal infection. The condition occurs either in infancy (usually between 2 and 12 weeks of age) or in the middle-aged or elderly and has a prognosis of lifelong recurrence.

Malassezia yeast organisms are probably not the cause but a cofactor linked to depressed helper T cells (seborrheic dermatitis is very common in AIDS); increased natural killer cells, which increase inflammatory cytokines; increased sebum levels; activation of the alternate complement pathway; and genetic susceptibility to a skin barrier dysfunction.[1] *Malassezia* species have lipase activity, which releases inflammatory arachidonic acid. Seborrheic dermatitis is aggravated by changes in humidity, scratching, emotional stress, diet, various medications, and androgen excess.

THERAPEUTIC CONSIDERATIONS

Nutrition

Food Allergy

Seborrheic dermatitis usually begins as cradle cap and, although not primarily an allergic disease, has been associated with food allergy (67% of patients exhibit some form of allergy by 10 years of age).[2]

Biotin

The underlying factor in infants may be a biotin deficiency.[3] A syndrome clinically similar to seborrheic dermatitis has been produced by feeding rats a diet high in raw egg white (high in avidin, a glycoprotein that binds biotin, making it unavailable for absorption). Because a large portion of the human biotin supply is provided by intestinal bacteria, it has been postulated that the absence of normal intestinal flora may be responsible for biotin deficiency in infants.[2] A number of articles have demonstrated successful treatment of seborrheic dermatitis with biotin in both the nursing mother and the infant.[3,4]

In adults, treatment with biotin alone is usually of no value.

Pyridoxine

Both the administration of desopyridoxine, which induces pyridoxine deficiency in humans, and the placing of rats on a pyridoxine-deficient diet cause dermatologic lesions indistinguishable from seborrheic dermatitis.[5] Despite these results, oral and parenteral applications of pyridoxine have shown little success. However, in the sicca form of the disorder (involvement of the scalp [dandruff], brow, nasolabial folds, and bearded area with varying degrees of greasy adherent scales on an erythematous base), all cases cleared completely within 10 days of local application of a water-soluble ointment containing 50 mg/g of pyridoxine. Other types of seborrheic dermatitis, particularly flexural and infected, did not respond to this mode of therapy.

In one study of patients with elevated levels of urinary xanthurenic acid, oral, parenteral, and local applications of pyridoxine all returned excretion levels to normal, implying transcutaneous absorption of pyridoxine.[5,6] These results are clouded, however, by those of another study indicating that the improvement from topical application may be due more to reduction in sebaceous secretion rate by the ointment itself, the added pyridoxine having no effect.[7]

The patient should be checked for exposure to pyridoxine antimetabolites. Examples are the hydrazine dyes (U.S. Food Drug and Cosmetic Act [FD&C] yellow no. 5) and drugs (isoniazid and hydralazine), dopamine, penicillamine, oral contraceptives, and excessive protein intake.[8]

Botanical Medicines

Aloe vera

Aloe vera gel can be quite helpful when applied topically. In one double-blind trial in people with seborrheic dermatitis, the application of a 30% crude aloe emulsion cream twice a day for 4 to 6 weeks produced improvements in scaling and itching in 62% of subjects compared with improvements in only 25% of the placebo group.[9]

Melaleuca alternifolia

M. alternifolia (tea tree) oil has demonstrated activity against *Malassezia* species, which may be of benefit in the treatment of seborrheic dermatitis. Honey and cinnamic acid have similar activity.[10] A study of 126 patients using 5% tea tree oil shampoo showed 41% improvement in severity versus 11% in the placebo group.[11] Tea tree oil may be added to the patient's favorite shampoo as a way of increasing compliance.

Homeopathic Therapy

A 2002 study evaluated the efficacy of a homeopathic combination remedy in the control of seborrheic dermatitis and chronic dandruff. The homeopathic therapy of Kali brom 1x, Natrum brom 2x, Niccolum sulf 3x, and Natrum mur 6x (potassium bromide, sodium bromide nickel sulfate, and sodium chloride) was studied in a placebo crossover trial in 41 patients with seborrheic dermatitis and/or chronic dandruff. At the end of 10 weeks, all patients crossed over to the active medication under a different label for an additional 10 weeks in an open-study format. Twenty-nine patients completed the 10-week blinded portion of the study. After 10 weeks of treatment, the disease state of the patients receiving active medication showed significant improvement compared with that of the patients receiving placebo ($P < 0.04$). Ten weeks after crossover, the placebo patients experienced improvement as well ($P < 0.01$).[12]

THERAPEUTIC APPROACH

Although the optimal approach to treating all patients with seborrheic dermatitis is not clear at this time, effective therapy is available for most patients. In infants, alleviation of the biotin deficiency and control of the food allergies are key. For adults, using *Aloe vera* and *M. alternifolia*oil is the primary therapy.

Diet

The physician should detect and treat food allergens. In nursing infants, the food allergies of the mother should be considered.

Supplements

- Biotin: 1 mg daily for infants[13]
- Homeopathic combination remedy once a day

Topical Treatments

- Pyridoxine ointment: 50 mg/g (in water-soluble base)
- *Aloe vera* gel: Apply twice a day to affected areas.
- Melaleuca oil: 5% solution (may be added to patient's shampoo of choice)

CHAPTER 208

Senile Cataracts

Michael T. Murray, ND

DIAGNOSTIC SUMMARY

- Clouding or opacity in the crystalline lens of the eye
- Absence or alteration of red reflex (small cataracts stand out as dark defects)
- Gradual loss of vision

GENERAL CONSIDERATIONS

Cataracts are the leading cause of impaired vision and blindness in the United States. Approximately 4 million people have some degree of vision-impairing cataract, and at least 40,000 people in the United States are blind because of cataracts. Cataracts are a source of a tremendous financial burden on our society; cataract surgery is the most common major surgical procedure performed in the United States each year (600,000 per year) for persons receiving Medicare benefits.

Cataracts may be classified by location and appearance of the lens opacities, by cause or significant contributing factor, and by age at onset. Many factors may cause or contribute to the progression of lens opacity, including ocular disease, injury, surgery, systemic diseases (e.g., diabetes mellitus, galactosemia), toxins, ultraviolet and near-ultraviolet light, radiation exposure, and hereditary disease.

Aging-related (or senile) cataracts are discussed in this chapter; diabetes- and galactose-induced cataracts (sugar cataracts) are discussed in Chapter 161.

The crystalline lens is obviously a vital component of the optical system owing to its ability to focus light (via changes in shape) while maintaining optical transparency. Unfortunately, this transparency diminishes with age. The majority of the geriatric population displays some degree of cataract formation. In the normal aging eye there is a progressive increase in size, weight, and density of the lens throughout life.

Cataract formation is characterized histopathologically by the following features:

- Fibrous metaplasia of the epithelium
- Liquefaction of fibers, resulting in morgagnian globule formation (drops of fluid beneath the capsule and between the lens fibers)
- Sclerosis (melding of fibers)
- Posterior migration and swelling of the epithelium

According to a topoanatomic classification, these basic alterations result in the following five types of cataracts:

- *Anterior subcapsular cataract:* Fibrous metaplasia of lens epithelium (usually follows iritis and adherence of the iris to the lens—posterior synechiae)
- *Anterior cortical cataract:* Liquefaction of lens fibers occurs and morgagnian globules form in the cortex anteriorly
- *Nuclear cataract:* An exaggeration of the normal aging-related melding of fibers in the nucleus
- *Posterior cortical cataract:* Liquefaction and globular degeneration of the posterior lens cortex
- *Posterior subcapsular cataract:* Epithelial cells migrate posteriorly under the capsule and form large irregular nucleated cells

About 75% of senile cataracts are cortical; the rest are nuclear. Clinically cortical cataracts take three forms:

- Spoke wheel, beginning in the periphery and coursing anteriorly and posteriorly to the nucleus

- Perinuclear punctate opacities
- Granular opacities under the posterior capsule (subcapsular cataracts)

THERAPEUTIC CONSIDERATIONS

The etiology of cataract formation is ultimately related to an inability to maintain normal homeostatic concentrations of Na^+, K^+, and Ca^{2+} within the lens. These abnormalities are apparently the result of decreased Na^+,K^+-ATPase activity,[1-6] a defect usually due to free radical damage to some of the sulfhydryl proteins in the lens, including Na^+,K^+-ATPase, which contains a sulfhydryl component.

In cataract formation, the normal protective mechanisms are unable to prevent free radical damage. The lens, like many other tissues of the body, depends on adequate levels and activities of superoxide dismutase (SOD), catalase, and glutathione (GSH) as well as adequate levels of accessory antioxidants such as lutein, vitamins E and C, and selenium to help prevent damage by free radicals. Individuals with higher dietary intakes of vitamin C and E, selenium, and carotenes (especially lutein) have a much lower risk of developing cataracts.[7] Several studies have shown that various nutritional supplements—multiple vitamin formulas, vitamins C and E, B vitamins (especially vitamin B_{12} and folic acid), and vitamin A—also offer significant protection against both nuclear and cortical cataracts.[8-11] Studies conducted by the Age-Related Eye Disease Study Research Group and others indicate that a combination of these nutrients will likely produce better results than any single nutrient alone or even limited combinations of three or less nutrients in the prevention of both age-related macular degeneration and cataracts (see Chapter 187 for more information).

Antioxidants

Lutein

Lutein, the yellow-orange carotene that offers significant protection against macular degeneration, also exerts protection against cataract formation.[12] Like the macula, the human lens concentrates lutein. In 1992, a prospective cohort study showed that consumption of spinach (high in lutein) was inversely related to the risk of cataracts severe enough to require extraction.[13] This initial investigation was followed by three prospective studies showing that intake of lutein was inversely associated with cataract extraction (20% to 50% risk reduction).[14-16] In a double-blind intervention trial, 17 patients clinically diagnosed with age-related cataracts were randomly assigned to receive dietary supplementation with lutein (15 mg), α-tocopherol (100 mg), or placebo three times a week for up to 2 years.[17] Visual performance (visual acuity and glare sensitivity) improved in the lutein group, whereas there was a trend toward the maintenance of visual acuity with α-tocopherol and a decrease with placebo supplementation.

Vitamin C

A high dietary intake of vitamin C from either dietary sources or supplements has been shown to protect against cataract formation.[8-11,18] In addition to preventing cataracts, antioxidant nutrients like vitamin C may offer some therapeutic benefits. Several clinical studies have demonstrated that vitamin C supplementation can halt cataract progression and in some cases significantly improve vision. For example, in a study conducted in 1939, a total of 450 patients with cataracts were started on a nutritional program that included 1 g/day of vitamin C, resulting in a significant reduction in cataract development.[1] Similar patients had previously required surgery within 4 years, but in the vitamin C–treated patients only a small handful needed surgery, and in most there was no evidence that the cataracts had progressed over the 11-year study period.

It appears that the daily dose of vitamin C necessary to increase the vitamin C content of the lens is 1000 mg.[2] The lens of the eye and active tissue of the body require higher concentrations of vitamin C. The level of vitamin C in the blood is about 0.5 mg/dL, whereas that in the adrenal and pituitary glands is 100 times that. In the liver, spleen, and lens of the eye, the vitamin C level is increased by at least a factor of 20. In order for these concentrations to be maintained, the body must generate enormous amounts of energy to pull vitamin C out of blood against this tremendous gradient. Keeping blood vitamin C concentrations elevated helps the body concentrate vitamin C into active tissue by reducing the gradient. That is probably why such a high dose is required to raise the vitamin C content of the lens.

In another study, 450 patients with incipient cataracts were started on a nutritional program including 1 g/day of vitamin C, which led to a significant reduction in cataract development.[3]

In a large double-blind trial, 11,545 apparently healthy U.S. male physicians 50 years or older without a diagnosis of cataract at baseline were randomly assigned to receive 400 IU of vitamin E or placebo on alternate days and 500 mg of vitamin C or placebo daily.[19] After 8 years of treatment and follow-up, there was no significant difference in cataract formation in the groups. This study may have failed to show benefit because it was below the threshold of 1 g/day of vitamin C.

Glutathione

A tripeptide composed of glycine, glutamic acid, and cysteine, GSH is found at very high concentrations in the lens. GSH plays a vital role in maintaining a healthy lens and has been postulated as a key protective factor against toxins of both intralenticular and extralenticular origin. It functions as an antioxidant, maintains reduced sulfhydryl bonds within the lens proteins, acts as a coenzyme of various enzyme systems, participates in amino acid transport with gamma-glutamyl transpeptidase, and is involved in cation transport.[4] GSH levels are diminished in virtually all forms of cataracts.

Ascorbic Acid and Glutathione Interactions. The antioxidants ascorbic acid (AA) and GSH work in close conjunction and are the most important of all the host-protective factors against the induction of cataracts. The reactions between them are as follows:

$$\text{AA} + \text{superoxide} \rightarrow \text{dehydroascorbate} + H_2O_2$$

Light may also cause oxidation of AA, leading to hydrogen peroxide formation as follows:

$$\text{AA} + \text{light} \rightarrow \text{dehydroascorbate} + H_2O_2$$

An interesting cycle is then set into motion. The dehydroascorbate and hydrogen peroxide produced are reduced by selenium-containing glutathione peroxidase, as follows:

$$2\text{GSH} + \text{dehydroascorbate} \rightarrow \text{GSSG} + \text{AA}$$

$$2\text{GSH} + H_2O_2 \rightarrow \text{GSSG} + 2H_2O$$

The oxidized glutathione (GSSG) serves as an inducer of the hexose monophosphate shunt, which provides the NADPH (nicotinamide adenine dinucleotide phosphate, reduced form)

necessary for reducing GSSG via riboflavin-dependent glutathione reductase, as follows:

$$GSSG + 2NADPH \rightarrow 2GSH + 2NADP$$

The NADP is reduced by hexose monophosphate dehydrogenase as follows:

$$NADP + \text{glucose-6-(P)} \rightarrow NADPH + \text{ribulose 5-(P)} + CO_2$$

This combination of enzymatic and nonenzymatic scavenging of free radicals is a key mechanism for the protection of the lens from photochemical and other forms of oxidative damage.

Selenium and Vitamin E

Selenium and vitamin E, both antioxidants, are known to function synergistically. The maintenance of proper selenium levels appears to be especially important because human lens glutathione peroxidase is selenium-dependent. Low selenium levels strongly promote cataract formation. Previous studies have shown that the selenium content in the cataractous human lens is only 15% of normal.[5]

A later study was conducted to better examine the role of selenium in cataract formation.[6] Selenium levels in the serum, lens, and aqueous humor were determined in 48 patients with cataracts and compared with levels in matched controls. Selenium levels in the serum and aqueous humor were found to be significantly lower in the patients with cataracts (serum, 0.28 mg/mL; aqueous humor, 0.19 mg/mL) than in normal controls (serum, 0.32 mg/mL; aqueous humor, 0.31 mg/mL). However, the selenium level in the lens itself did not significantly differ between the patients with cataracts and the controls.

The most important finding of the study was the decreased level of selenium in the aqueous humor in patients with cataracts. Excess hydrogen peroxide levels, up to 25 times normal, are found in the aqueous humor in patients with cataracts. An excess of hydrogen peroxide is associated with higher lipid peroxidation and altered lens permeability as a result of damage to the sodium-potassium pump. These changes ultimately leave the lens unprotected against free radical and sun damage. As a result, a cataract is formed. Because selenium-dependent glutathione peroxidase is responsible for the breakdown of hydrogen peroxide, it is obvious that low levels of selenium are a major factor in the development of a cataract.

As previously described, vitamin E supplementation alone does not slow the progression of cataract formation.[17] A double-blind study in which vitamin E was given at a dose of 500 IU daily also found that supplementation did not slow cataract formation.[20] In a 7-year trial, supplementation with vitamin E (400 IU) combined with vitamin C (500 mg) and beta-carotene (15 mg) had no effect on the development or progression of cataracts.[21]

Superoxide Dismutase

The activity of SOD is lower in the human lens than in other tissues owing to the higher levels of ascorbate and glutathione in the lens, and a progressive decrease in SOD is encountered in cataract progression. Oral supplementation is probably of little value because it does not affect tissue SOD activity.[22] Of greater value is supplementation with the trace mineral cofactors of SOD, the levels of which are greatly reduced in the cataractous lens (copper by > 90%; manganese by 50%; and zinc by > 90%).[23]

Catalase

Catalase is concentrated in the epithelial portion of the lens (anterior surface), with very low levels found in the rest of the lens. Its primary function is to reduce (to water and oxygen) the hydrogen peroxide formed from the oxidation of ascorbate.

Tetrahydrobiopterin

Pteridine compounds are believed to play a protective role against cataract formation via the prevention of oxidation and damage by ultraviolet light. This action prevents the formation of high-molecular-weight proteins in the lens. Tetrahydrobiopterin functions as an essential coenzyme in the hydroxylation of monoamines such as phenylalanine hydroxylase, tyrosine hydroxylase, and tryptophan hydroxylase. Studies of human senile cataracts have demonstrated decreased levels of pteridine-synthesizing enzymes and tetrahydrobiopterin.[24] Supplemental folic acid may help to compensate for this deficiency.

Other Nutritional Factors

Riboflavin

Lenticular GSH requires flavin adenine dinucleotide (FAD) as a coenzyme for GSH.[25,26] Deficiency of riboflavin, the precursor of FAD, is believed to enhance cataract formation by depressing GSH activity. Although riboflavin deficiency is fairly common in the geriatric population (33%), original studies demonstrating an association between riboflavin deficiency and cataract formation were followed by studies demonstrating no such association. The patient's riboflavin status can be determined by measuring GSH activity in red blood cells before and after stimulation with FAD.[26]

Although correction of the deficiency is warranted, no more than 10 mg/day of riboflavin should be prescribed for patients with cataracts, because it is a photosensitizing substance—superoxide radicals are generated by the interaction of light, ambient oxygen, and riboflavin/FAD. Riboflavin and light (at physiologic levels) have been used experimentally to induce cataracts. The evidence appears to suggest that excess riboflavin does more harm than good in patients with cataracts.

Amino Acids

Methionine is a component of the lenticular antioxidant enzyme methionine sulfoxide reductase and a precursor of cysteine, a component of GSH. Cysteine, along with the other amino acid precursors of GSH, has been shown to be of some aid in cataract treatment.[27]

Zinc, Vitamin A, and Beta-Carotene

The antioxidants zinc, vitamin A, and beta-carotene are known to be essential to normal epithelial integrity. Adequate amounts of these nutrients are vitally important to the health of the epithelial portion of the lens. In particular, beta-carotene may act as a filter, protecting against light-induced damage to the fibrous portion of the lens. Beta-carotene is the most significant of the singlet oxygen free radical scavengers and is used in treating photosensitive disorders.[28] However, in long-term studies, beta-carotene supplementation (50 mg on alternate days) on its own has been found to have no impact on cataract prevention in either women or men.[29,30]

Melatonin

Melatonin is a very efficient free radical scavenger and antioxidant that can neutralize hydroxyl and peroxyl radicals as well as enhance endogenous and exogenous antioxidant efficiency. In animal models, melatonin has been an effective inhibitor of DNA damage, lipid peroxidation, and cataract formation. Melatonin is present at significant levels in the cell nucleus, aqueous cytosol, and lipid-rich cellular membranes.[31]

Dairy Products

Cataracts often develop in infants with a homozygous deficiency of either galactokinase or galactose-1-phosphate uridyl transferase and in laboratory animals fed a high-galactose diet. Abnormalities of galactose metabolism can be identified by measurements of the activity of these enzymes in red blood cells. It has been suggested that such abnormalities are an important mechanism in approximately 30% of cataracts.[26] However, this mechanism of cataract formation appears to be significant only in diabetic cataract formation and is probably not relevant to senile cataract formation (for further discussion, see Chapter 161).

Heavy Metals

A number of heavy metals have been shown to have higher concentrations in both the aging lens and the cataractous lens. Although the levels are higher in the latter, the significance of this finding is unknown.[23]

The cadmium concentration is two to three times higher in cataractous lenses than in lenses of age-matched controls. Because cadmium displaces zinc from binding in enzymatic proteins by binding to the sulfhydryl groups, it may contribute to deactivation of free radical quenching and other protective/repair mechanisms.

Other elevated elements of unknown significance are bromine, cobalt, iridium, and nickel.[23]

Botanical Medicines

A number of excellent choices from the botanical world are available to help with antioxidant mechanisms. They are discussed here.

Flavonoid-Rich Extracts

Among the best may be flavonoid-rich extracts from *Vaccinium myrtillus* (bilberry), *Vitis vinifera* (grape seed), and *Pinus maritima* (pine bark). The occurrence of cataracts in rats can be retarded by changing their diet from a commercial laboratory chow to a "well-defined diet."[32] Preliminary research suggests that flavonoid components in the well-defined diets may be responsible for the protective effects.[33]

Of the flavonoid-rich extracts, bilberry anthocyanosides may offer the greatest protection. In one human study, bilberry extract plus vitamin E stopped progression of cataract formation in 97% of 50 patients with senile cortical cataracts.[34]

Hachimijiogan

An ancient Chinese herbal formula, Hachimijiogan, has been shown to raise the antioxidant level of the lens of the eye.[35] This activity may explain its use in treatment of cataracts for hundreds of years. According to clinical research, its therapeutic effect is quite impressive in the early stages of cataract formation. In one study, 60% of the subjects receiving Hachimijiogan noted significant improvement, 20% of the group showed no progression, and only the remaining 20% displayed progression. Hachimijiogan contains the following eight herbs (per 24 g):

- *Rehmania glutinosa:* 6000 mg
- *Poria cocos sclerotium:* 3000 mg
- *Dioscorea opposita:* 3000 mg
- *Cormus officinalis:* 3000 mg
- *Epimedium grandiflorum:* 3000 mg
- *Alisma plantago:* 3000 mg
- *Astragalus membranaceus:* 2000 mg
- *Cinnamonum cassia:* 1000 mg

THERAPEUTIC APPROACH

In cases of marked visual impairment, cataract removal and lens implantation may be the only alternative. As with most diseases, prevention or treatment at an early stage is most effective. Free radical damage appears to be the primary factor in the induction of senile cataracts, so avoidance of oxidizing agents and promotion of free radical scavenging are critical to successful treatment. The patient should avoid direct ultraviolet light, bright light, and photosensitizing substances; wear protective lenses when outdoors; and greatly increase intake of antioxidant nutrients. Progression of the pathologic process can be stopped and early lesions can be reversed. However, significant reversal of well-developed cataracts does not appear to be possible at this time. Because the geriatric population is especially susceptible to nutrient deficiencies, every effort should be made to ensure that the patient is ingesting and assimilating adequate macronutrients and micronutrients.

Diet

Patients should avoid rancid foods and other sources of free radicals and increase consumption of legumes (high in sulfur-containing amino acids), yellow vegetables (carotenes), and foods rich in vitamins E and C.

Supplements

- High-potency multivitamin/multimineral formula
- Lutein: 5 to 15 mg/day
- Vitamin C: 1 g one to three times a day
- Vitamin E: 600 to 800 IU/day
- Selenium: 400 mcg/day
- L-Cysteine or *N*-acetylcysteine: 400 mg/day
- L-Glutamine: 200 mg/day
- L-Glycine: 200 mg/day

Botanical Medicines

- Bilberry extract (25% anthocyanidin content): 80 mg three times a day
- Hachimijiogan formula: 1000 mg three times a day

Local Treatment, *1798*

DIAGNOSTIC SUMMARY

- Abrupt onset of sore throat, fever, malaise, nausea, and headache
- Throat red and edematous, with or without exudate
- Tender cervical lymph nodes
- Positive rapid detection of streptococcal antigen
- Group A streptococci on throat culture

GENERAL CONSIDERATIONS

Signs and symptoms of streptococcal pharyngitis ("strep throat") resemble those of viral pharyngitis. Of children with sore throat, 15% to 36% have pharyngitis caused by group A beta-hemolytic streptococci (GABHS). Slightly lower percentages occur in adults as throat cultures yield GABHS in less than 20% of adult patients presenting clinically with a sore throat. However, it must be kept in mind that 10% to 25% of the general, asymptomatic population are carriers for group A streptococci; therefore, the true number of cases of pharyngitis due to GABHS is probably lower than reported.

Rapid "strep" screens that detect the presence of group A streptococcal antigens are a major clinical advancement. Because definitive diagnosis with a positive culture usually takes 2 days, antibiotic therapy during this period for presumed group A strep throat leads to unnecessary exposure to antibiotics and a greater likelihood of the development of antibiotic-resistant organisms. Rapid strep screens, such as the Strep A OIA test, have now shown excellent sensitivity and specificity and will soon replace throat culture as the diagnostic gold standard.[1] In addition, the hope is that the use of these rapid strep screens will eliminate the unnecessary use of antibiotics. That said, these tests remain underutilized, because one analysis found that they were performed on only 53% of cases of acute pharyngitis where an antibiotic was prescribed.[2] Many physicians continue to rely on antibiotics as a precaution against the sequelae of streptococcal pharyngitis even in the absence of a positive diagnosis, resulting in unnecessary prescriptions for antibiotics. Even in positive cases, antibiotics may not be necessary, because strep throat is usually a self-limited disease and most research has shown that clinical recovery is similar in cases where antibiotics are prescribed and those where they are not.[3-5]

The primary concern about not using antibiotics is the development of the "nonsuppurative poststreptococcal syndromes" (rheumatic fever, poststreptococcal glomerulonephritis, etc.). However, antibiotic administration does not significantly reduce the incidence of these sequelae. In developed countries, most cases of rheumatic fever and glomerulonephritis due to group A beta-hemolytic strep throat occur because the affected persons do not consult a physician.[6] It is also important to point out that, although the dogma holds that acute rheumatic fever can be caused only by group A streptococcal infection of the upper respiratory tract, epidemiology indicates that streptococcal pyoderma is a major cause in the Aboriginal people of Northern Australia and perhaps other high-incidence communities. In contrast, in settings where rheumatic fever has become rare, the group A streptococcal strains causing pharyngitis are of relatively low virulence in terms of causing rheumatic fever.[6]

At present it appears that the use of antibiotics should be reserved those patients who are suffering from severe infection or whose sore throats are unresponsive to therapy

(i.e., no response after 1 week of immune supportive therapy) and those with a prior history of rheumatic fever or glomerulonephritis. Penicillin, amoxicillin, erythromycin, and first-generation cephalosporins are the recommended antibiotics for the treatment of sore throat due to GABHS. Amoxicillin tends to be the most common prescription to children primarily for compliance reasons, whereas macrolides like erythromycin and cephalosporins have been recommended as the best first-line antibiotics, because penicillin fails to eradicate the streptococci in more than 20% of patients.[7] The primary reason for this is the presence of beta-lactamase–positive organisms (*Staphylococcus aureus* and *Bacteroides* species), which shield streptococci by deactivating the penicillin. In these instances, stronger antibiotics, such as a cephalosporin, may be required.[8] Nonetheless, because of the low cost and absence of resistance, penicillin is still regarded as an acceptable first choice.[9]

Antibiotics are often praised for their role in effectively eliminating rheumatic fever as a serious concern. However, the dramatic decrease in the incidence of rheumatic fever began before the advent of effective antibiotics.[10] As for the eradication of most infectious diseases, improvements in socioeconomic, hygienic, and nutritional conditions were more important than the liberal use of penicillin. The present attack rates after a streptococcal infection are 0.4% to 2.8% for rheumatic fever and 0.2% to 20% for glomerulonephritis. Obviously such a wide range of reported sequelae makes accurate evaluation of the risk difficult.

THERAPEUTIC CONSIDERATIONS

The primary therapeutic consideration is the status of the patient's immune system. If the patient's immune system is functioning well, the illness will be short-lived. Enhancing general immune function, as described in Chapter 56, may shorten the course. In cases of poor immune function, every effort should be made to strengthen the immune system by following the recommendations given in that chapter.

Vitamin C

During the 1930s there was considerable interest in the relationship between malnutrition and the development of the sequelae of streptococcal pharyngitis. Both experimental animal work and epidemiologic surveys demonstrated a correlation between vitamin C deficiency and the development of sequelae. Rheumatic fever is virtually nonexistent in the tropics, where vitamin C intake is higher. Elsewhere, as many as 18% of children in high-risk groups have subnormal serum levels of vitamin C.

When streptococcus-infected, vitamin C–deficient, rheumatic fever–susceptible guinea pigs are supplemented with vitamin C, the development of rheumatic fever is totally prevented.[11,12] Uncontrolled clinical studies have demonstrated very positive results when children were given orange juice supplementation. Unfortunately, this promising line of research appears to have been dropped, probably owing to the advent of supposedly effective antibiotics.

Hydrastis canadensis and *Echinacea*

The guidelines for enhancing the immune system, as presented in Chapter 56 are particularly strongly indicated for streptococcal pharyngitis. In addition, the botanicals *H. canadensis* and *Echinacea* species are well respected as supports for the immune system during GABHS infections. The berberine alkaloid of *Hydrastis* exerts antibiotic activity against streptococci and, perhaps more importantly, has been shown to inhibit the attachment of group A streptococci to pharyngeal epithelial cells. *Echinacea* also exerts action against streptococcal infection. To promote the spread of colonies, streptococci secrete large amounts of hyaluronidase. This enzyme is inhibited by *Echinacea* as well as by many bioflavonoids. *Echinacea* also inactivates group A streptococci and reduces the proinflammatory response to strep infection[13] as well as promoting greater phagocytosis, natural killer cell activity, and properdin levels. See Chapters 86 and 97 for further discussion.

Pelargonium sidoides (South African Geranium)

Extracts from the rhizomes and tubers of *P. sidoides* have been shown to exert a number of effects that are beneficial in upper respiratory tract infections, particularly acute bronchitis, an indication for which it is an approved drug in Germany (see Chapter 153). *P. sidoides* has demonstrated immune-enhancing effects as well as antibacterial effects and the ability to prevent adhesion of bacteria to epithelial cells.[14] In a double-blind study, an extract of *P. sidoides* (EPs 7630) was shown to be superior to placebo for the treatment of non-GABHS tonsillopharyngitis in children.[15] A total of 143 children, aged 6 to 10 years, with non-GABHS tonsillopharyngitis were given either EPs 7630 or placebo (20 drops three times daily) for 6 days. The decrease in the Tonsillopharyngitis Severity Score from baseline (day 0) to day 4 was 7.1 points with EPs 7630, and 2.5 points in the placebo group. Treatment with EPs 7630 reduced the severity of symptoms and shortened the duration of illness by at least 2 days, consistent with the results seen in acute bronchitis. Although this study was in non-GABHS, it does raise the possibility that *P. sidoides* may have benefit in GABHS.

Bacteriotherapy

Colonizing the throat with group A non–beta-hemolytic streptococci may prove to be an effective treatment for recurrent group A beta-hemolytic streptococcal pharyngitis. In a double-blind study, 130 patients with recurrence of group A beta-hemolytic streptococcal pharyngotonsillitis received antibiotic treatment for 10 days, followed by 10 days of spray treatment with either placebo or group A non–beta-hemolytic streptococcal alpha-streptococci.[16] The clinical recurrences (bacteriologically verified) in the alpha-streptococci- and placebo-treated patient groups were 2% and 23%, respectively, in patients given spray for at least 5 days. No side effects were reported.

In another double-blind study, a total of 342 patients with verified GABHS pharyngitis by the rapid strep test and culture received antibiotic treatment for 10 days, followed by 10 days of alpha-streptococcal or placebo spray treatment. Pharyngeal status, throat culture, and adverse events were investigated up to 75 days after treatment. The frequencies of bacteriologically verified clinical recurrence at the last valid visit after 45 to 75 days were 19% and 30%, respectively—a statistically significant difference. Recolonization with alpha-streptococci seemed to hinder late recurrences of GABHS pharyngotonsillitis.[17]

Lactoferrin

Low concentrations of bovine lactoferrin have significantly hindered the in vitro invasion of cultured epithelial cells by group A streptococci isolated from patients with pharyngitis. The ability of lactoferrin to decrease streptococcal invasion was confirmed in a trial carried out in 12 children with pharyngitis and already scheduled for tonsillectomy. A lower number of intracellular group A streptococci were

found in tonsil specimens from children treated for 15 days before tonsillectomy with both oral erythromycin (500 mg three times daily) and lactoferrin gargles (100 mg three times daily) than in those from children treated with erythromycin alone (500 mg three times daily).[18]

THERAPEUTIC APPROACH

For further information, consult Chapter 56. If antibiotics are used, follow the recommendations for supplementation with *Lactobacillus acidophilus* given in Chapter 116.

Supplements

- Vitamin C: 500 mg every 2 hours
- Bioflavonoids: 1000 mg/day
- Zinc: 30 mg/day

Botanical Medicines

Echinacea species:
- Dried root (or as tea): 0.5 to 1 g/day
- Freeze-dried plant: 325 to 650 mg/day
- Juice of aerial portion of *E. purpurea* stabilized in 22% ethanol: 2 to 3 mL/day
- Tincture (1:5): 2 to 4 mL (0.5 to 1 tsp)/day
- Fluid extract (1:1): 2 to 4 mL (0.5 to 1 tsp)/day
- Solid (dry powdered) extract (6.5:1 or 3.5% echinacoside): 150 to 300 mg/day

Hydrastis canadensis

The dosage of *H. canadensis* should be based on berberine content. Because there is a wide range of quality in goldenseal preparations, standardized extracts are recommended.
- Dried root or as infusion (tea): 2 to 4 g three times a day
- Tincture (1:5): 6 to 12 mL (1.5 to 3 tsp) three times a day
- Fluid extract (1:1): 2 to 4 mL (0.5 to 1 tsp) three times a day
- Solid (powdered dry) extract (4:1 or 8% to 12% alkaloid content): 250 to 500 mg three times a day

Pelargonium sidoides

Dosage recommendations for EPs 7630 or equivalent preparation:

Adults: 1.5 mL three times a day or a 20-mg tablet three times a day for up to 14 days

Children: age 7 to 12 years, 20 drops (1 mL) three times a day; age 6 years or less, 10 drops (0.5 mL) three times a day

Local Treatment

The patient should gargle with lactoferrin (100 mg) dissolved in water three times a day. An alternative recommendation is a saltwater gargle consisting of 1 tablespoon of salt per 240 mL of warm water.

DIAGNOSTIC SUMMARY

- Profuse malodorous white to green discharge from the vagina.
- Discharge usually has a pH greater than 4.5, a weak amine odor, and large numbers of white blood cells and trichomonads on wet mount.
- Vulvovaginal pruritus, burning, and/or irritation.
- Vulva and introitus usually show erythema.
- Cervix may or may not have a mottled erythema—"strawberry cervix" (less than 5%).
- Dysuria and/or dyspareunia may be present.
- Rule out trichomoniasis in males exhibiting signs of prostatitis, urethritis, or epididymitis.

GENERAL CONSIDERATIONS

Trichomonas vaginalis infection is a common cause of vaginal irritation in women and is the most common nonviral sexually transmitted disease in the world. It is estimated to affect 5 million women in the United States each year alone. One in five women in the United States will have trichomoniasis at some time in her life. Aside from these alarming statistics, there are other reasons for taking trichomonal infections seriously, as follows[1,2]:

- Gonorrhea and trichomoniasis are common coexisting infections, with up to 40% of women with trichomoniasis having gonorrhea and vice versa.
- Trichomoniasis is a common cause (90%) of cervical erosion and therefore may be a factor in malignant transformation.
- Trichomoniasis may complicate interpretation of Papanicolaou smears, increasing the number of false-positive results.
- Trichomoniasis raises the rate of sterility among males and females, in the latter as a result of salpingitis and in the former because of toxic products that decrease the motility of spermatozoa.
- The rate of postpartum fever and discharge is higher in women in whom *T. vaginalis* infection occurs at delivery.
- Neonates infected via the birth canal may manifest serious illness (rare).
- Prostatitis and epididymitis are common in infected males.
- Trichomoniasis increases transmission and infectivity of human immunodeficiency virus (HIV), such that HIV-seropositive men with concomitant trichomoniasis may have a sixfold higher concentration of HIV RNA in their seminal plasma.
- Infection may confuse and/or complicate other urinary or genital tract problems.

DIAGNOSIS

T. vaginalis is a flagellate 15 to 18 micrometers in length. It is shaped like a turnip, with three to four anterior flagella and one posterior flagellum mounted in an undulating membrane. It is transmitted via sexual intercourse. Although women in the past have been thought to be the primary reservoir for *Trichomonas* and men merely the vector, the medical literature now suggests that men are also reservoirs.[3,4]

Diagnosis is made from clinical signs and symptoms (see the diagnostic summary), saline wet mount, and culture. Trichomonal cultures (using the Feinberg

Trichomonas medium) have recently been advocated to improve diagnostic sensitivity. Although the wet mount is one of the most commonly used and quickest methods to achieve a diagnosis, multiple studies have demonstrated that, compared with culture, the sensitivity of a wet mount ranges from only 45% to 60%.[1,2] In men, a reliable culture site has not been established, and cultures from urine and seminal samples have consistently afforded a low yield. Among patients with trichomonal vaginitis, the organism can be cultured from the vagina and paraurethral glands in 98%, from the urethra in 82%, and from the endocervix in 13%. In only 56% to 65% of patients is *T. vaginalis* seen on a Papanicolaou smear, thus making the smear an unreliable form of diagnosis.[1,2] However, recent data suggest that the positive predictive value of this test is acceptable for a diagnosis of trichomoniasis when it is found incidentally on Papanicolaou smear. A meta-analysis found a sensitivity of 57% and a specificity of 97%.[5]

Rapid point-of-care tests for trichomonal vaginitis are now available; they include the OSOM Trichomonas Rapid Test (Genzyme Diagnostics, Cambridge, Mass), an immunochromatographic capillary-flow dipstick technology, and the Affirm VP III (Becton Dickinson, Franklin Lakes, NJ), a nucleic acid probe test that evaluates for trichomonal vaginitis, *Gardnerella vaginalis*, and *Candida albicans*.[1] Both of these tests are performed on vaginal secretions and have a sensitivity greater than 83% and a specificity greater than 97%. The results of the OSOM Trichomonas Rapid Test are available in about 10 minutes, and the results of the Affirm VP III are available within 45 minutes. These tests tend to greatly assist physicians in the accurate and timely diagnosis of trichomoniasis.

Trichomonal Vaginitis

Sexual transmission is the clear route of *Trichomonas* infection. Prevalence is highest among women with multiple sex partners and in those with other sexually transmitted infections. Transmission rates from men to women seem to be high, because an 80% to 100% prevalence rate is found in the female partners of infected men.[4] In the female, *T. vaginalis* usually infests the vagina and urethra. However, infection may involve the endocervix, Bartholin glands, Skene glands, or bladder. The vagina appears to be a good reservoir for the organism. Under stimulation of estrogen, the vaginal walls are well glycogenated—essential for *T. vaginalis* to thrive. Prepubescent and postmenopausal women seldom have symptomatic trichomonal infections.

In addition to estrogen, an elevated pH increases susceptibility to *Trichomonas*. The normal adult vagina maintains a pH of 3.5 to 4.5 owing to the metabolism of free glucose into lactic acid by vaginal *Lactobacillus acidophilus*. A decrease in the number of lactobacilli raises pH. *Trichomonas* organisms grow optimally at a vaginal pH of 5.5 to 5.8. Other conditions that increase vaginal pH are as follows:

- Progesterone, which rises in the latter half of the menstrual cycle and during pregnancy
- Excess intravaginal secretions (i.e., cervical mucus)
- Overgrowth of certain bacteria, such as *Streptococcus* and *Proteus*

Trichomonas in the Male

Although the incidence is lower in men, 5% to 15% of cases of nongonococcal urethritis are estimated to be caused by trichomonal infections.[1,2] The estimated transmission rate is 70% for men who have had sexual contact with infected women in the previous 48 hours.[2] Men with *T. vaginalis* are most often asymptomatic, yet mild cases of urethritis, prostatitis, and epididymitis have been reported. As might be expected, trichomoniasis is a factor in male infertility.[4] Trichomonads have been identified in semen, urethral discharge, urine, and prostatic fluid and have been found in the prostatic secretions and semen in up to 23% of men with chronic nongonococcal prostatitis.[6]

Although men were thought to be the only vectors for *Trichomonas*, the parasite is now known to persist in the male reproductive tract. The reinfection of treated females who are sexually active is well documented.[4] Therefore, treatment of both sex partners is necessary. Furthermore, among both women and men, the association of *T. vaginalis* with enhanced HIV acquisition and transmission has been well documented.[2]

THERAPEUTIC CONSIDERATIONS

Conventional Treatment

Conventional therapy of trichomoniasis involves metronidazole[7] and tinidazole, a second-generation nitroimidazole used to treat metronidazole-resistant infection. Randomized controlled trials comparing tinidazole (2-g single oral dose) and either metronidazole (2-g single oral dose) or short-course metronidazole have demonstrated parasitologic cure rates of 86% to 100% for all treatments, although tinidazole is slightly more effective but also more expensive. In a Cochrane Database meta-analysis of randomized trials comparing short-course therapy with tinidazole and short-course therapy with metronidazole for trichomoniasis, metronidazole had significantly higher rates of parasitologic failure, clinical failure, and adverse effects.[8] Again, in order to reduce recurrence rates, sex partners should be treated at the same time.

Common side effects of metronidazole and tinidazole are nausea, vomiting, metallic taste, and gastrointestinal upset. With long-term high-dose use, rare occurrences of peripheral neuropathy have been reported.

If metronidazole or inidazole treatment is chosen, probiotic supplementation should accompany it. In the treatment of bacterial vaginosis, administration of vaginal insertion with *L. acidophilus* has led to cure rates superior to those with metronidazole.[9,10] This suggests some benefit in vaginal trichomoniasis, given the frequent disruption of proper vaginal flora in these women.

Diet

Dietary factors affect the body's ability to defend itself against foreign invaders and substances both directly and indirectly. As with any infection, it is not the pathogenicity of the organism but rather the "fertility of the soil" that allows the organism to grow and flourish. A well-balanced diet high in natural fiber (vegetable, fruits) and low in fat, sugar, and refined carbohydrates aids immune function (see Chapter 56 for more discussion) and may discourage any concomitant overgrowth of *Candida.*

Lifestyle

Depression and anxiety have been associated with exacerbations of trichomonal infections. Therefore, efforts to reduce stress are definitely indicated. Reduction may be achieved by a variety of means, including exercise and meditation.

The practice of safe sex or abstinence (during infection) also lowers the incidence of infection and reinfection.

Nutritional Supplements

In addition to the basic supplements for immune support described in Chapter 56, zinc supplementation appears to be an important consideration in the treatment of trichomonal infections in both men and women. The antimicrobial spectrum of zinc is broad and comprises many potential genitourinary pathogens, including *T. vaginalis* as well as *Candida albicans* and *Chlamydia trachomatis* and many viruses.[11] Trichomonads are readily killed by zinc at a concentration of 0.042% (6.4 mmol/L), a concentration that can occur in the prostatic fluid of men. The zinc concentration of prostatic fluid ranges from 0.015% to 0.10% (2.3 to 15.3 mmol/L).[11] This finding suggests that persistent trichomonal infections in men may be due to a low-level zinc deficiency. Zinc sulfate (220 mg twice daily for 3 weeks) has been recommended as a possible treatment for trichomonal infections that are refractory to metronidazole.[12]

For women with drug-resistant trichomoniasis, zinc douches in combination with metronidazole may provide welcome relief. In a small study, the women with recalcitrant trichomoniasis (4 months to 4 years culture-positive despite conventional treatment), all became culture-negative through the use of a combination of 1% zinc sulfate douching (for 3 days after each menstrual period) and 1.6 to 2.2 g/day of metronidazole (suppositories plus oral administration).[13]

Topical Trichomonacides

Povidone-Iodine

Iodine has long been recognized as a highly potent trichomonacide. Povidone-iodine (PVP) has a broad therapeutic effect in killing a large number of different microorganisms that cause vaginitis, including *T. vaginalis.*[14,15] PVP (iodine, which is absorbed into polyvinyl pyrrolidine) has several advantages over iodine in that it has little sensitizing potential, does not sting, is water-soluble, and washes out of clothing.

A success rate of 98.1% has been reported in patients with intractable trichomonal, monilial, nonspecific, and mixed vaginitis for a 2-week treatment regimen using PVP (Betadine) preparations.[16,17] Other studies suggest a 28-day course of povidone-iodine pessaries, particularly if the patient is using oral contraceptives.[18]

Propolis

An ethanol extract of propolis (150 mg/mL) has been shown to have a 100% lethal effect in vitro on the protozoans *T. vaginalis* and *Toxoplasma gondii* after 24 hours of contact.[19] This extract has also been shown to diminish the inflammation associated with trichomonal vaginitis.

Essential Oils

The diverse antimicrobial action of essential oils has been well demonstrated. Many possess strong antitrichomonal properties. In a study of 40 essential oils tested for their ability to kill *Trichomonas, Mentha piperita* (peppermint) and *Lavandula angustifolia* (lavender) had the fastest killing effects (20 and 15 minutes, respectively).[20]

Melaleuca alternifolia

M. alternifolia (tea tree) oil is a powerful cidal agent (see Chapter 102). Commonly used as a germicidal agent in Great Britain and Australia, a 40% solution of tea tree oil has been found to be a highly effective treatment.[21] The 40% solution of the oil produced no irritation, burning, or other side effects. Daily vaginal douches with a 0.4% solution of *Melaleuca* oil in 1 L of water was also found to be effective.[22]

Berberine-Containing Botanicals

The plant alkaloid berberine sulfate has been shown in vitro to inhibit the growth of several protozoa, including *Entamoeba histolytica*, *Giardia lamblia*, and *T. vaginalis*.[23,24] No clinical trials of this agent have been reported in trichomonas vaginalis (see Chapter 97 for further discussion).

THERAPEUTIC APPROACH

Given the risk of serious sequelae of trichomoniasis and the high success rate of conventional pharmaceutical intervention, systemic metronidazole should be carefully considered as a possible first-line treatment along with simultaneous and subsequent naturopathic therapies to decrease the risk of future recurrence and to treat some of the contributing underlying susceptibilities. Naturopathic therapies may be used as first-line therapy in patients who are allergic to metronidazole or are pregnant. The use of metronidazole in pregnancy remains somewhat of a controversy despite its apparent lack of teratogenic action, because data have accumulated that despite the role of *T. vaginalis* in perinatal morbidity, metronidazole treatment may actually increase the risk of preterm birth.[25,26] Discussion with the patient of such factors as diet, sexual habits, and lifestyle is a must. The clinician should inform the patient that *Trichomonas* infection is a sexually transmitted disease and that treatment of the sex partners is necessary to prevent reinfection. During the treatment, sexual intercourse should be avoided. If intercourse does occur, a condom must be used.

Diet

The patient should decrease the consumption of refined carbohydrates, alcohol, and fats and increase intake of fiber.

Nutritional Supplements

- Zinc (picolinate): 10 to 15 mg/day
- Vitamin E: 200 IU/day
- *L. acidophilus:* 5 to 10 billion live bacteria twice a day orally as well as the intravaginal application in vaginal trichomoniasis. See Chapter 116 for further discussion.

Topical Treatments

- Betadine douche, pessary, or saturated tampon: twice a day for 14 days
- *M. alternifolia* oil (40% solution): swabbed on affected area two times/day *or* used as a douche, 1 L of a 0.4% solution twice a day or a suppository, one at night
- Zinc sulfate douche: 1% solution twice a day
- *Lactobacillus* insertions or douches a day, preferably in the morning

CHAPTER 211

Urticaria

Michael Traub, ND, DHANP, FABNO, and Michael T. Murray, ND

DIAGNOSTIC SUMMARY

- Urticaria (hives): Well-circumscribed erythematous wheals with raised serpiginous borders and blanched centers that may coalesce to become giant wheals; limited to the superficial portion of the dermis.
- Angioedema: Eruptions similar to those of urticaria but with larger well-demarcated edematous areas that involve subcutaneous structures as well as the dermis.
- Chronic versus acute: Recurrent episodes of urticaria and/or angioedema of less than 6 weeks' duration are considered acute, whereas attacks persisting beyond this period are designated chronic. When no underlying cause is found, chronic urticaria is referred to as chronic idiopathic urticaria.
- Special forms: Special forms have characteristic features—dermographism, cholinergic urticaria, solar urticaria, cold urticaria.

INTRODUCTION

Urticaria is named for the stinging nettle plant *Urtica dioica,* which is known to contain histaminic acid. Urticaria is a localized pruritic edema of the skin characterized by white or pink papules or plaques. The lesions are consistent with lesions of histamine-induced wheals. The lesions may develop variable erythema and coalesce to form plaques. About 50% of patients with urticaria experience angioedema—a deeper, less well-defined edema of the subcutaneous and soft tissues.

Urticaria and angioedema are relatively common conditions: It is estimated that they occur in 15% to 25% of the general population.[1] Although persons in any age group may experience acute or chronic urticaria and/or angioedema, young adults (postadolescence through the third decade of life) are most often affected.[2,3]

The basic pathophysiology of urticaria involves the release of inflammatory mediators from mast cells or basophilic leukocytes, both of which have high-affinity receptors for immunoglobulin E (Ig E).[4] Although this inflammation classically occurs as a result of IgE–antigen complexes interacting with these cells, other non–IgE-mediated mechanisms are probably also critical in many patients with urticaria, including prostaglandins, leukotrienes, cytokines and chemokines. A growing body of evidence shows that at least 40% of patients with chronic idiopathic urticaria have clinically relevant functional autoantibodies to the high-affinity IgE receptor on basophils and mast cells. The term *autoimmune urticaria* is used for this subgroup of patients presenting with continuous ordinary urticaria.[5]

PATHOPHYSIOLOGY

The signs and symptoms of acute and chronic urticaria show consistent patterns despite the many diverse etiologic and initiating factors (see later) that have been found, yet the pathogenesis cannot be entirely ascribed to any one mechanism. However, at present, it appears that mast cells and mast cell–dependent mediators play the most prominent role in the pathogenesis of urticaria.[6]

Mast cells are widely distributed throughout the body and are found primarily near small blood vessels, particularly in the skin. The granule-containing mast cell is a secretory cell capable of releasing both preformed and newly synthesized molecules, termed *mediators*. These mediators (listed in Box 211-1) play key roles in

BOX 211-1 Mast Cell–Derived Mediators

Preformed, rapidly released:
- Histamine
- Eosinophil chemotactic factors of anaphylaxis (ECF-A)
- Eosinophil chemotactic oligopeptides
- Neutrophil chemotactic factor
- Superoxide anions
- Exoglycosidases (β-hexosaminidase, β-δ-galactosidase,* β-glucuronidase)
- Serotonin*
- Arylsulfatase A

Secondary or newly generated:
- Slow-reacting substances (SRS-A): leukotrienes (LT) C, LTD, LTE
- Prostaglandins
- Monohydroxyeicosatetraenoic acids (HETEs)
- Hydroperoxyeicosatetraenoic acids (HPETEs)
- Thromboxanes
- Platelet-activating factor (PAF)*
- Prostaglandin-generating factor of anaphylaxis (PGF-A)

Preformed, granule-associated:
- Heparin
- Proteases (chymotrypsin/trypsin)
- Peroxidase*
- Superoxide dismutase*
- Arylsulfatase B
- Inflammatory factors of anaphylaxis (IFA)*

*Found in mast cells of species other than human.
Data from Keahey TM. The pathogenesis of urticaria. Dermatol Clin 1985;3:13-28.

the pathogenesis of both immunologic and nonimmunologic inflammatory reactions. The three distinct sources of mediators are as follows:
- Preformed mediators, which are contained in the granules and are released immediately
- Secondarily formed mediators, which are generated immediately or within minutes by the interaction of the primary mediators and nearby cells and tissues
- Granule matrix–derived mediators, which are preformed but slowly dissociate from the granule after discharge and remain in the tissues for hours

The most common immunologic mechanism is mediated by IgE.

The early vascular changes appear to be the result of mast cell–dependent vasoactive mediators, particularly histamine and some secondarily generated end products of arachidonic acid metabolism. The wheal-and-flare reactions occur within minutes of initiation and last 30 to 60 minutes.

Histamine and other mediators can be released by other nonallergic mechanisms as well. Neuropeptides are known to cause mast cell degranulation and may well be involved in dermographism and emotional exacerbation of urticaria. The more prolonged and delayed reactions reflect leukocytic infiltration in response to the release of mast cell granule–derived chemotactic factors. These late-phase reactions develop over time and are characterized by erythema, edema, and induration beginning within 2 hours and lasting 12 to 24 hours. Leukocyte infiltration may contribute to the urticarial tissue response by inducing a second wave of mast cell activation or by releasing toxic lysosomal enzymes and mediators characteristic of the type of infiltrating cell.

The actual events initiated by the mediators also depend on the tissues into which they are released. For example, the release of histamine into the skin primarily produces pruritus and vascular permeability, whereas histamine release into the lungs may induce bronchospasm.

Helicobacter pylori has been implicated as a causative agent in chronic urticaria. However, two reviews of the trials showing the benefit of *H. pylori* eradication in patients with chronic urticaria have arrived at conflicting conclusions, one saying the benefit is weak and another that it is statistically significant.[7,8] Including testing for *H. pylori* seems reasonable; if positive, a decision to proceed with this management should be considered carefully in the context of relative harms/burdens and benefits as well as patient values and preferences.

CAUSES OF URTICARIA

Fundamental to the treatment of urticaria is the recognition and control of causative factors.

Physical Urticarias

Urticaria can be produced as a result of reactions to various physical stimuli. The most common forms of physical urticarias are dermographic, cholinergic, and cold urticarias (Table 211-1). These are briefly described here. Less common types of physical urticarias or angioedema are as follows[2]:
- Contact
- Solar
- Pressure
- Heat contact
- Aquagenic
- Vibratory
- Exercise-induced

Dermographism

Dermographism or dermographic urticaria is a readily elicited whealing of the skin that evolves rapidly when moderate amounts of pressure are applied. It may occur as a result of simple contact with furniture, garters, bracelets, watch bands, towels, or bedding.

The incidence of dermographic urticaria has been estimated at 1.5% to 5% in the general population. The most common type of physical urticaria, it is found twice as frequently in women as in men, with the average age at onset being in the third decade. The incidence is much greater among the obese, especially those who wear tight clothing.

Dermographic lesions usually start within 1 to 2 minutes of contact as an erythema, which is replaced within 3 to 5 minutes by edema and surrounding reflex urticaria. Maximal edema is usually produced within 10 to 15 minutes. Although the erythema generally regresses within an hour, the edema can persist up to 3 hours.

Dermographism may be associated with other diseases, including[2]:
- Parasitosis
- Insect bites
- Neuropsychiatric disorders
- Hormonal changes
- Thyroid disorders
- Pregnancy
- Menopause
- Diabetes
- Immunologic alterations

TABLE 211-1 **Clinical Aspects of Physical Urticarias**

TYPE	ELICITING STIMULUS	TIME OF ONSET	DURATION OF LESION	DIAGNOSTIC TEST	ASSOCIATED SYMPTOMS
Dermographic urticaria (tarda)	Stroking, scratching (rubbing for red dermographism)	2-5 min (0.5-5 hr)	1-5 hr (48 hr)	Firm stroking of skin	Headache, malaise
Cholinergic urticaria	Physical exercise + overheating; mental stress	2-20 min	30-60 min	Bicycling, running, sauna	Headache, gastrointestinal upset, wheezing, salivation, lacrimation, syncope
Cold urticaria	Cold contact	2-5 min	1-2 hr	Ice cube, cold arm bath, cold air	Wheezing, syncope
Solar urticaria	Light of varying wavelengths	2-15 min	0.25-3 hr	Phototest	Wheezing, dizziness, syncope
Pressure urticaria	Pressure	3-8 hr	8-24 hr	Locally applied weights	Flulike syndrome, fever, leukocytosis, arthralgias
Heat contact urticaria	Contact with heat	2-15 min	30-60 min	Hot arm bath	Gastrointestinal upset, dizziness, fatigue, wheezing, dyspnea
Aquagenic urticaria	Contact with water	2-30 min	30-60 min	Bath, compresses	None
Vibratory angioedema	Vibration	0.5-4 min	1 hr	Vibrating motor	Faintness, headache
Exercise-induced anaphylaxis	Exercise after a heavy meal	2-5 min	10-30 min	Exercise	Flushing, headache, disorientation, glottis edema, dyspnea, collapse
Familial cold urticaria	Cold wind, change from cold to warm air	0.5-3 hr	48 hr	Cold wind and subsequent rewarming	Tremor, headache, arthralgias, fever

Data from Czarnetzki BM. Urticaria. New York: Springer-Verlag, 1986.

- Other urticarias
- During or following drug therapy
- Infection with *Candida albicans*
- Angioedema
- Hypereosinophilia

Cholinergic Urticaria

Cholinergic, or heat-reflex, urticaria is the second most common physical urticaria. These lesions, which depend on the stimulation of the sweat gland via cholinergic afferent fibers, consist of pinpoint wheals surrounded by reflex erythema. The wheals arise at or between follicles and develop preferentially on the upper trunk and arms.

The three basic types of stimuli that may produce cholinergic urticaria are passive overheating, physical exercise, and emotional stress. Typical eliciting activities, in addition to physical exercise, may include taking a warm bath or sauna, eating hot spices, and drinking alcoholic beverages. The lesions usually arise within 2 to 10 minutes after provocation and last for 30 to 50 minutes.

A variety of systemic symptoms may also occur, suggesting a more generalized mast cell release of the mediators than in the skin. Headache, periorbital edema, lacrimation, and burning of the eyes are common symptoms. Less common symptoms are nausea, vomiting, abdominal cramps, diarrhea, dizziness, hypotension, and asthma attacks.[2]

Cold Urticaria

Cold urticaria is an urticarial and/or angioedematous reaction of the skin when it comes into contact with cold objects, water, or air. Lesions are usually restricted to the area of exposure and develop within a few seconds to minutes after the removal of the cold object and rewarming of the skin. The lower the object's or element's temperature, the faster the reaction. Children with cold urticaria have a higher risk of anaphylaxis, especially triggered by swimming.[9]

Widespread local exposure and generalized urticaria can be accompanied by the following symptoms:

- Flushing
- Headaches
- Chills
- Dizziness
- Tachycardia
- Abdominal pain
- Nausea
- Vomiting
- Muscle pain
- Shortness of breath
- Wheezing
- Unconsciousness

Cold urticaria has been observed to accompany a variety of clinical conditions, including the following[1]:

- Viral infections
- Parasitic infestations
- Syphilis
- Multiple insect bites
- Penicillin injections
- Dietary changes
- Stress

The association of cold urticaria with infectious mononucleosis is well established. Other conditions associated with cold urticaria

are cryoglobulinemia and myeloma, in which cold urticaria may precede the diagnosis by several years.[2]

Autoimmune Urticaria

Although much remains unknown regarding the specific pathophysiologic mechanisms underlying most cases of chronic urticaria, a minority seem to have an autoimmune basis. Research has discovered that a significant percentage of patients previously categorized as having idiopathic urticaria have autoantibodies to IgE or the FcεRIα subunit of the high-affinity IgE mast cell receptor.[10] Studies have identified these autoantibodies in 24% to 76% of patients with chronic urticaria. From a clinical perspective, these patients tend to have a somewhat more severe, prolonged course of disease. Middle-aged women are disproportionately represented in the population of patients with urticaria, and higher rates of autoimmunity in this group, particularly for thyroid disease, may account for this preponderance. Thyroid autoantibodies are found more frequently in patients with these IgE receptor autoantibodies (see later discussion of thyroid).

Autoimmune diseases are well known to be associated with bowel permeabilities.[11-14] Because subclinical impairments of small bowel enterocyte function have been postulated to induce a higher sensitivity to histamine in the digestive tract,[15] it makes sense from a naturopathic standpoint to treat overt and subclinical digestive system permeabilities to decrease systemic inflammatory responses to endotoxins in these autoimmune conditions.

Drugs

Drugs make up the leading cause of urticarial reactions in adults. In children, the reactions are usually due to foods, food additives, or infections.[2]

Most drugs are composed of small molecules incapable of inducing antigenic/allergenic activity on their own. Typically, they act as haptens that bind to endogenous macromolecules, ultimately causing the production of hapten-specific antibodies. Alternatively, drugs can interact directly with mast cells to induce degranulation. Many drugs have been shown to produce urticaria. Box 211-2 provides a condensed list.[16] The two most common urticaria-inducing drugs, penicillin and aspirin, are briefly discussed here.

Penicillin

Antibiotics, including penicillin and related compounds, are the most common cause of drug-induced urticaria. The allergenicity of penicillin in the general population is thought to be at least 10%. Nearly 25% of these individuals display urticaria, angioedema, or anaphylaxis on ingestion of penicillin.[2,17]

An important characteristic of penicillin is that it cannot be destroyed by boiling or steam distillation. This is a problem because penicillin and related contaminants can exist undetected in foods. To what degree penicillin in the food supply contributes to urticarial reactions is not known. However, urticaria and anaphylactic symptoms have been traced to penicillin in milk,[18] soft drinks,[19] and frozen dinners.[20] In one study of 245 patients with chronic urticaria, 24% had positive skin test results and 12% had positive results on the radioallergosorbent test for penicillin sensitivity.[21] Of those 42 patients sensitive to penicillin, 22 experienced clinical improvement with a dairy-free diet, whereas only 2 out of 40 patients with negative skin test results experienced improvement with the same diet. This study would seem to provide indirect evidence of the importance of penicillin in the food supply in urticaria.

In an attempt to provide direct evidence, penicillin-contaminated pork was given to penicillin-allergic volunteers. No significant reactions were noted other than transient pruritus in two volunteers.[22] Penicillin in milk appears to be more allergenic than penicillin in meat.[18] Presumably the reason is that penicillin can be degraded into more allergenic compounds in the presence of carbohydrate and metals, suggesting that penicillin in milk may be more allergenic than artificially contaminated meat.[18]

BOX 211-2 Drugs That Can Cause Urticaria

- Acetylsalicylic acid
- Allopurinol
- Antimony
- Antipyrines
- Barbiturates
- Bismuth
- Chlorhydrate
- Chlorpromazine
- Corticotropin (adrenocorticotropic hormone)
- Eucalyptus
- Fluorides
- Gold
- Griseofulvin (cold urticaria)
- Insulin
- Iodines
- Liver extract
- Menthol
- Meprobamate
- Mercury
- Morphine, opium
- Paraaminosalicylic acid
- Penicillin
- Phenacetin
- Phenobarbital
- Pilocarpine
- Poliomyelitis vaccine
- Potassium sulfocyanate
- Procaine
- Promethazine
- Quinine
- Reserpine
- Saccharin
- Thiamine chloride
- Thiouracil

Data from Andrews GC. Andrews' diseases of the skin, ed 7. Philadelphia: WB Saunders, 1982:131.

Aspirin and Nonsteroidal Antiinflammatory Drugs

Urticaria is a more common indicator of aspirin sensitivity than is asthma (see Chapter 147). The incidence of aspirin sensitivity in patients with chronic urticaria is at least 20 times greater than that in normal controls.[23-27] Studies (summarized in Table 211-2)[28-57] have demonstrated that 2% to 67% of patients with chronic urticaria are sensitive to aspirin.

Aspirin inhibition of cyclooxygenase apparently shunts eicosanoid metabolism toward leukotriene synthesis, thereby increasing smooth muscle contraction and vascular permeability. In addition, aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) have been shown to increase gut permeability dramatically and may alter the normal handling of antigens.[53,58] NSAIDs are also known be associated with prolonged and more pronounced autoreactivity in urticaria.[57] The daily administration of 650 mg of aspirin for 3 weeks has been shown to desensitize patients with urticaria and aspirin sensitivity. While taking the aspirin, patients also became nonresponsive to foods to which they usually reacted, such as pineapple, milk, egg, cheese, fish, chocolate, pork, strawberries, and plums.[59] Others have noted this effect in patients with asthma, but they have also found that the effect disappears within 9 days after the treatment is stopped, suggesting the loss of effect or a possible placebo response.[60]

Food-Related Causes

Food Allergy

IgE-mediated urticaria can occur on the ingestion of a specific reaginic antigen. Although any food can be the agent, the most common offenders are milk, fish, meat, eggs, beans, and nuts.[2,17,61-67] Other allergens are citrus, kiwis, peanuts, and apples.[61]

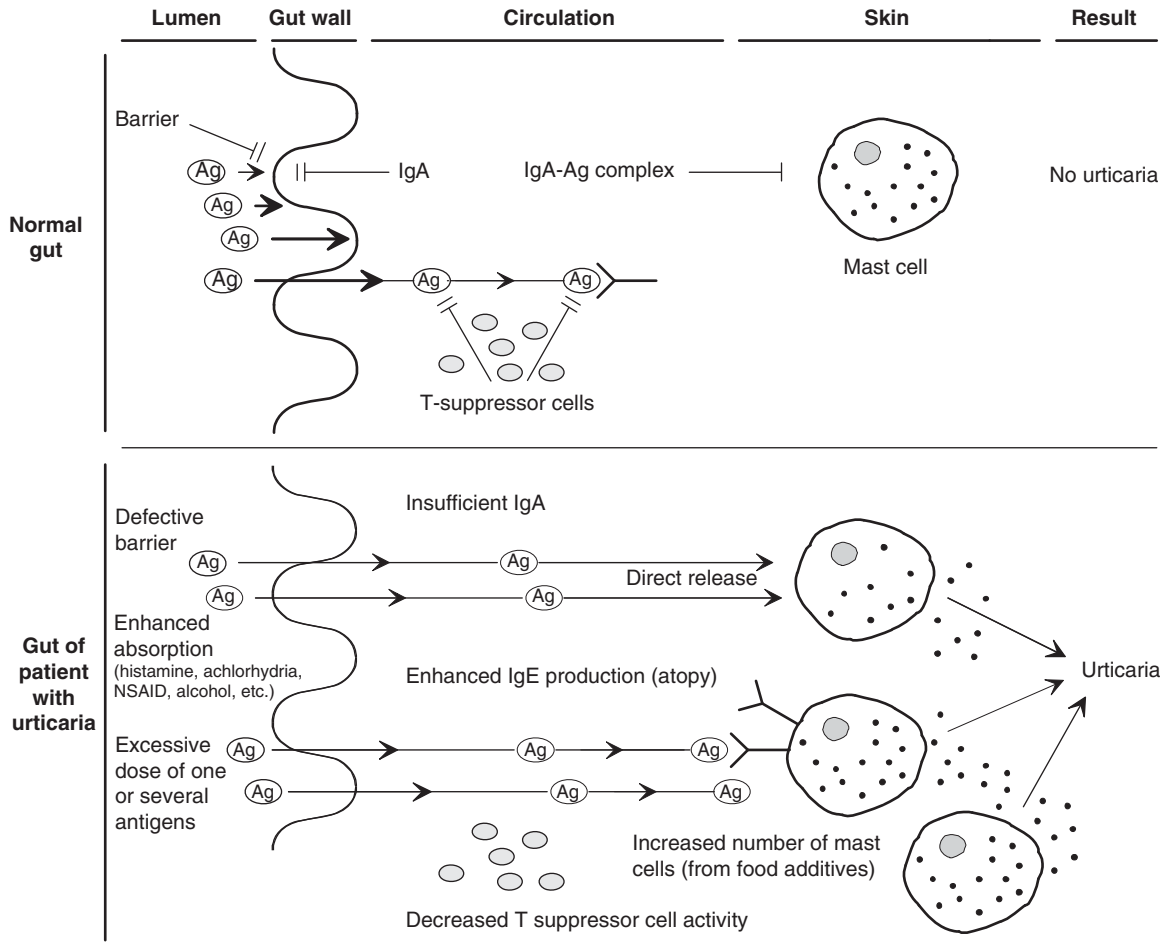

FIGURE 211-1 Hypothetical model of immune defense in the normal and urticarial gut.

Individuals with atopy are most likely to experience urticaria as a result of IgE-related mechanisms, although reports confirm the presence of pseudoallergic reactions, whereby direct mast cell histamine release is involved in this reactivity. Aromatic volatile ingredients in tomatoes, wine, and culinary herbs (basil, fenugreek, cumin, dill, ginger, coriander, caraway, turmeric, parsley, pepper, rosemary, and thyme) have been considered the initiating factors in some of these non-IgE events.[68,69]

Food allergies may contribute greatly to the increased permeability of the gut in urticaria. A basic requirement for the development of a food allergy is the absorption of the allergen through the intestinal barrier. Several factors are known to significantly increase gut permeability, including alcohol, NSAIDs, vasoactive amines ingested in foods or produced by bacterial action on essential amino acids, and possibly many food additives (see Chapter 20 for a full discussion). Gut permeabilities are also associated with autoimmune conditions.[11-14] Because chronic urticaria is now known to be at least partially related to an autoimmune process (see earlier discussion of autoimmune urticaria), it is possible that, depending on the genetic susceptibility of individual, these bowel permeabilities may play a key role in the instigation of immune activity and its prolongation, leading to chronic urticaria.

In addition, several investigators have reported alterations in gastric acidity, intestinal motility, and the function of the small intestine and biliary tract in up to 85% of patients with chronic urticaria.[70-74] Selective IgA deficiency, gastroenteritis, hypochlorhydria or achlorhydria, and other disruptive factors reported in patients with chronic urticaria may temporarily or permanently alter the barrier and immune function of the gut wall, predisposing an individual to allergic sensitization.

In one study of 77 patients with chronic urticaria, 24 (31%) were diagnosed as achlorhydric and 41 (53%) were shown to be hypochlorhydric.[72] Treatment with hydrochloric acid and a vitamin B complex gave impressive clinical results, highlighting the importance of correcting any underlying factor in the treatment of chronic urticaria (see Chapter 24).

Although IgE-mediated reactions are thought to predominate in immunologic urticaria, it has been suggested that IgG-mediated reactions are probably responsible for the majority of adverse reactions to foods, as seen in general practice (see Chapter 54). IgG antigen-antibody complexes are capable of promoting complement activation and the subsequent generation of anaphylatoxins that promote mast cell degranulation. This could be a significant factor in some cases of urticaria.

Figure 211-1 summarizes the basic aspects of a hypothetical model of immune defense in the normal gut and the urticarial gut.

Food Colorants

Food additives are a major factor in many cases of chronic urticaria in children. Colorants (azo dyes), flavorings (salicylates, aspartame), preservatives (benzoates, nitrites, sorbic acid), antioxidants (hydroxytoluene, sulfite, gallate), and emulsifiers/stabilizers (polysorbates, vegetable gums) have all been shown to produce urticarial reactions in sensitive individuals.*

The importance of the control of food additives was well demonstrated in a study of 64 patients with common urticaria. After 2 weeks on an additive-free diet, 73% of the patients had a significant reduction in symptoms. The diet strictly forbade preservatives, dyes, and antioxidants. No fruits or refined sugars were allowed except honey. Rice, potatoes, and unprocessed cereals were allowed, as well as fresh milk.[75]

Tartrazine. In 1959, the azo dye tartrazine (Food, Drug and Cosmetic Act [FD&C] Yellow no. 5) was the first food dye reported to induce urticaria.[76] Tartrazine is one of the most widely used colorants. It is added to almost every packaged food as well as many drugs, including some antihistamines, antibiotics, steroids, and sedatives.[77] Reactions to this food additive are so common that its use has been banned in Sweden.[78]

In the United States, the average daily per capita consumption of certified dyes is 15 mg, of which 85% is tartrazine. Among children, consumption is usually much higher. Tartrazine sensitivity has been calculated as occurring in 0.1% of the population.[79]

Tartrazine sensitivity is extremely common (20% to 50%) in individuals sensitive to aspirin.[17,77] Like aspirin, tartrazine is a cyclooxygenase inhibitor and a known inducer of asthma, urticaria, and other allergic conditions, particularly in children. Inhibition of cyclooxygenase by tartrazine or aspirin apparently shunts eicosanoid metabolism toward leukotriene synthesis, thereby increasing smooth muscle contraction and vascular permeability.

In addition, tartrazine, as well as benzoate and aspirin, increases the production of the lymphokine leukocyte inhibitory factor.[79] This results in an increase in perivascular mast cells and mononuclear cells. Histologic examination of patients with urticaria shows that more than 95% have an increase in perivascular mast cells and mononuclear cells.[80]

Table 211-2 summarizes the findings in studies using provocation tests to determine sensitivity to tartrazine and other food additives in patients with urticaria. Rates have varied from 5% to 46%. Diets eliminating tartrazine as well as other azo dyes and food additives in sensitive individuals have in many cases been shown to be of great benefit. These studies are summarized in Table 211-3. Table 211-4 shows a recommended test battery.[81]

TABLE 211-4 **Test Battery for Patients With Recurrent Urticaria**

DAY	SUBSTANCE(S) TESTED	AMOUNT (MG)
1	Control (lactose)	100,000

Food Flavorings

Salicylates. A broad range of salicylic acid esters are used to flavor foods such as cake mixes, puddings, ice cream, chewing gum, and soft drinks. The mechanism of action of these agents is thought to be similar to that of aspirin.[17]

Salicylates are also found naturally in many foodstuffs. It is estimated that daily salicylate intake from foods is in the range of 10 to 200 mg/day.[82] Because this is very close to the level of salicylates used in clinical testing (usually 300 mg), dietary salicylate may be a significant factor in aspirin-sensitive individuals.

Most fruits, especially berries and dried fruits, contain salicylates. Raisins and prunes have the highest amounts. Salicylates are also found in appreciable amounts in candies made of licorice and peppermint. Moderate levels of salicylate are found in nuts and seeds. Vegetables, legumes, grains, meat, poultry, fish, eggs, and dairy products typically contain insignificant levels of salicylates. Salicylate levels are especially high in some herbs and condiments, including curry powder (turmeric), paprika, thyme, dill, and oregano. Although the intake of these herbs and spices is relatively small, they can make a contribution to total dietary salicylate.[82]

Other Flavoring Agents. Other flavoring agents, such as cinnamon, vanilla, menthol, and other volatile compounds, may produce urticaria in some individuals.[17] For example, the artificial sweetener aspartame has been shown to induce urticaria.[87]

Food Preservatives

Benzoates. Benzoic acid and benzoates are the most commonly used food preservatives. Although the incidence of adverse reactions to these compounds is thought to be less than 1% for the general population, the frequency of positive challenges in patients with chronic urticaria varies from 4% to 44%, as illustrated in Table 211-2.

Fish and shrimp frequently contain extremely high quantities of benzoates. This may be one reason why adverse reactions to these foods are so common in patients with urticaria.

Butylated Hydroxytoluene and Butylated Hydroxyanisole. Butylated hydroxytoluene (BHT) and butylated hydroxyanisole are the primary antioxidants used in prepared and packaged foods. Typically, 15% of patients with chronic urticaria test positive to oral challenge with BHT.[30,43,52,56] The use of chewing gum containing BHT was enough to induce urticaria in one patient.[84]

Sulfites. Sulfites, like tartrazine, have been shown to induce asthma, urticaria, and angioedema in sensitive individuals.[85,86] The source may be varied, because these compounds are ubiquitous in foods and drugs. They are typically added to processed foods to prevent microbial spoilage and keep them from browning or changing color. The earliest known use of sulfites was in the treatment of wines with sulfur dioxide by the Romans. Sulfites are sprayed on fresh foods such as shrimp, fruits, and vegetables. They are also used as antioxidants and preservatives in many pharmaceuticals. Sulfites have caused such a wide range of health problems, such as asthma and urticaria, that their use on fresh fruits and vegetables (except potatoes) was banned in the United States in 1986.[78]

The average person consumes an average of 2 to 3 mg/day of sulfites. Wine and beer drinkers typically consume up to 10 mg/day, and individuals who frequent restaurants for meals may ingest up to 150 mg/day.[85]

Normally, the enzyme sulfite oxidase metabolizes sulfites to safer sulfates, which are excreted in the urine. People with a poorly functioning sulfoxidation system, however, have an increased ratio of sulfite to sulfate in their urine. Sulfite oxidase depends on the trace mineral molybdenum. Although most nutrition textbooks list molybdenum deficiency as uncommon, an Austrian study of 1750 patients found that 41.5% were molybdenum deficient.[87]

Food Emulsifiers and Stabilizers

A variety of compounds is used to emulsify and stabilize many commercial foods to ensure that the solids, oils, and liquids do not separate out. Most of the foods containing these compounds are heterogeneous, because they usually contain antioxidants, preservatives, and dyes. Polysorbate in ice cream has been reported to induce urticaria, and vegetable gums such as acacia, gum arabic, tragacanth, quince, and carrageenan may also induce urticaria in susceptible individuals.[17]

Infections

Infections are a major cause of urticaria in children.[2] Apparently, in adults, immunologic tolerance occurs to many microorganisms owing to repeated massive antigen exposure. The role of bacteria, viruses, and yeast *(C. albicans)* in urticaria is briefly reviewed here. Chronic *Trichomonas* infections have also been found to cause urticaria.

Bacteria

As noted previously, *H. pylori* has been implicated in chronic urticaria. Bacterial infections contribute to urticaria in two other major settings—acute streptococcal tonsillitis in children and chronic dental infections in adults. In the first setting, acute urticaria predominates, whereas in the second, chronic urticaria predominates.[2]

Viruses

Hepatitis B is the most common cause of virally induced urticaria. One study found that 15.3% of patients with chronic urticaria had anti–hepatitis B surface antibodies.[88] Urticaria has also been strongly linked to infectious mononucleosis and may develop several weeks before clinical manifestations. The incidence of urticaria during infectious mononucleosis is 5%.[2]

Candida albicans

The association between *C. albicans* and chronic urticaria has been suggested in several clinical studies. The number of patients with chronic urticaria who react positively to an immediate skin test with *Candida* antigens is 19% to 81%, compared with 10% to 15% of normal subjects.[32,89-95] It appears that sensitivity to *C. albicans* is an important factor in at least 25% of patients with chronic urticaria.[92] Approximately 70% of patients with a positive skin reaction also react to oral provocation tests using foods prepared with yeasts.

Treatment with nystatin has demonstrated that elimination of the organism can achieve a cure in a number of individuals with positive skin test results, although a placebo response cannot be ruled out. However, more patients have responded to a "yeast-free" diet than to simple elimination of the organism in clinical trials. The yeast-free diet employed excluded breads, buns, sausage, wine, beer, cider, grapes, sultanas, marmite, Bovril, vinegar, tomato, ketchup, pickles, and prepared foods containing food yeasts. For example, in a study of 49 patients with proved sensitivity to *Candida,* 9 showed responses to a 3-week course of nystatin, whereas 18 became symptom free only after adopting the yeast-free diet.[92] This finding would seem to support the importance of diet along with elimination of the yeast.

Further support for the importance of diet can be found in a study of 36 patients with a positive skin-prick test response to *Candida*. Only 3 patients became asymptomatic with nystatin alone, compared with 23 with diet therapy after the nystatin therapy.[93]

Desensitizing patients to *C. albicans* with the use of a *Candida* cell wall extract has also demonstrated encouraging results in some patients, although the treatment of these individuals also included increasing gastrointestinal fermentation and acidity as well as elimination of yeast.[94,95]

THERAPEUTIC CONSIDERATIONS

Psychological Aspects

In one retrospective study involving 236 cases of chronic urticaria, psychological factors, such as stress, were reported to be the most common primary cause.[96] Stress appears to play an important role through a reduction of intestinal secretory IgA levels.

In one study of 15 patients with chronic urticaria, relaxation therapy and hypnosis were shown to provide significant benefit.[97] Patients were given an audiotape and asked to use the relaxation techniques described on the tape at home. At a follow-up examination 5 to 14 months after the initial session, 6 patients were free of hives and 7 others reported improvement.

Ultraviolet Light Therapy

Ultraviolet light has been shown to be of some benefit to patients with chronic urticaria.[98,99] Both ultraviolet A and ultraviolet B light therapies have been used. Patients with cold, cholinergic, and dermographic urticarias display the greatest therapeutic response.

Thyroid

The association of thyroid disease and autoimmunity with urticaria has been established for decades.[100-105] The prevalence of antithyroid antibodies in the normal population has been estimated at 3% to 6%, and they are commonly found in association with other autoimmune conditions, such as pernicious anemia and vitiligo.[103] A subset of patients with chronic urticaria may be best helped by suppressing thyroiditis, by thyroid hormone therapy (as described in the following studies), by surgery, or by antithyroid medication.

One study evaluated a group of 624 patients with presumed idiopathic chronic urticaria and angioedema. From these, 90 patients were found to have thyroid autoimmunity.[104] Forty-six of these patients were treated with L-thyroxine therapy, 8 of whom had remission within 4 weeks of therapy. Four patients with high thyroid antibody titers had repeated exacerbations when therapy was discontinued and had repeated remissions when therapy with L-thyroxine was resumed. Although in most cases treatment with L-thyroxine did not improve the patient's urticaria or angioedema, a few did demonstrate a dramatic response.

Another study reported that thyroid hormone replacement therapy dramatically improved chronic urticaria in patients who had normal thyroid function but had evidence of thyroid autoimmunity. Of 7 patients with chronic urticaria, 5 were started on thyroid hormone; doses were increased in 2. Their urticaria resolved within 2 to 4 weeks, at which time the thyroid therapy was discontinued. In 5 patients, the symptoms returned within 4 weeks, then resolved within 4 weeks of restarting the hormone therapy. Antithyroid antibodies did not correlate with clinical response.[104]

There have been cases in which resolution of chronic urticaria associated with thyrotoxicosis has also been seen in patients treated with antithyroid medication and in those treated with radioactive iodine.[103] Subclinical hypothyroidism is an increasingly recognized entity and may underlie the thyroid-urticaria association in some cases.

Although the usefulness of thyroid hormone therapy in patients who are euthyroid and have chronic urticaria has not been demonstrated in a controlled trial, looking for thyroid autoimmunity is certainly warranted in cases refractory to other forms of therapy.

Traditional Chinese Medicine/Acupuncture Therapy

Acupuncture has long been used in traditional Chinese medicine (TCM) to effectively treat urticaria[106,107] and type I allergic conditions.[108] Known as "wind wheal," urticaria is also referred to by Chinese practitioners as the "hidden rash," owing to its ephemeral nature.

Three standard TCM etiologies are considered for urticaria. Urticarial disease due to wind heat typically manifests as red rashes with pruritus. Wind damp etiology correlates with lighter-colored rashes and a heavy sensation in the body. Alternatively, red rashes that appear with concomitant epigastric or abdominal pain and diarrhea or constipation are considered a derivation of stomach and small intestinal heat. Acute urticaria can be easily and effectively treated with acupuncture, in which LI11 (Quchi), Sp10 (Xuehai), Sp6 (Sanyinjiao), and S36 (Zusanli) are the acupuncture points most commonly prescribed.[108] Auricular acupuncture may also accompany body acupuncture points for enhanced effect. External herbal washes with *Fructus arctii* (burdock) are also used in TCM.

Controlled studies are needed to fully elucidate the benefits of TCM for allergic disease and urticaria, but given its safety and history of effective use, it is certainly worth a try.

Supplements

Vitamin B_{12}

Vitamin B_{12} has been anecdotally reported to be of value in the treatment of acute and chronic urticaria.[109,110] Although serum vitamin B_{12} levels are normal in most patients, additional vitamin B_{12} appears to be of value. However, because injectable vitamin B_{12} was used, the placebo effect (see Chapter 7) cannot be ruled out.

Quercetin

Considering the importance of mast cell degranulation in the pathogenesis of urticaria, quercetin's significant in vitro activity as a mast cell stabilizer (and inhibitor of many of the pathways of inflammation; see Chapter 95) suggests that it may be very useful in treating urticaria. This possibility is strengthened by the observation that sodium cromoglycate (at 200 to 400 mg four times daily), a compound similar to quercetin, confers excellent protection against the development of urticaria and angioedema in response to ingested food allergens.[111]

Fish Oil

Three patients with salicylate-induced urticaria experienced alleviation of symptoms following dietary supplementation with omega-3 fatty acids. All three patients experienced severe urticaria, asthma requiring systemic steroid therapy, and anaphylactic reactions. After dietary supplementation with 10 g daily of fish oil providing 3000 mg EPA+DHA for 6 to 8 weeks, all three experienced

complete or virtually complete resolution of symptoms, allowing discontinuation of systemic corticosteroid therapy. Symptoms relapsed after dose reduction.[112]

DIAGNOSIS

Physical Evaluation and History

A thorough history and physical evaluation are imperative for the proper diagnosis of urticaria and should include a careful history listing all medications, supplements, and botanicals. Evaluation should also detail travel, recent infection, occupational exposure, timing and onset of lesions, morphology, associated symptoms, family medical history, and pre-existing allergies. Contact sensitivities such as latex allergy[113] and exposure to physical stimuli should be documented. History of tattoos should be explored for possible correlations. A diet and lifestyle diary that chronicles date and time, foods eaten, major activities, bowel and urine habits, and stress should be gathered in order to fully to characterize the potential temporal relationships of urticaria with specific ingested foods and activities. A comprehensive physical examination can also uncover important diagnostic clues that may help to diagnose comorbidities.

Laboratory Testing

The appropriate role of laboratory testing and studies in chronic urticaria remains controversial.[10] One review of 29 large studies of laboratory testing in chronic urticaria, involving 6462 patients, demonstrated no relationship between numbers of identified diagnoses and numbers of performed tests.[114] This review noted that systemic diseases (which excluded physical urticarias, allergens, infections, and psychological causes) were identified and believed to be related causally to the urticaria only in 1.6% of patients; these diseases included vasculitis, thyroid disease, systemic lupus erythematosus, other rheumatic disease, hereditary angioedema, and hematologic or oncologic conditions.

The use of screening skin testing for food allergies is also controversial.[10,59] It is known that many patients with food-induced urticaria have diagnosed themselves without the help of a specialist. Skin testing for foods in the patient with chronic urticaria is fraught with false-positive and false-negative results. In the absence of a specific history suggestive of a particular food allergy (history of exposure and time course of subsequent symptoms consistent with typical food allergy), such skin testing can be counterproductive, particularly in patients with dermatographism and "twitchy" mast cells.[10]

If symptoms do not remit after proper history and physical examination have been performed and the therapies listed here have been tried, it may be useful to perform a complete blood count with differential, urinalysis, erythrocyte sedimentation rate measurement, liver function tests, antinuclear antibody titer measurements, and thyroid panel with antithyroid autoantibody measurements. These tests may help ferret out most of the uncommon cases with a detectable but unsuspected underlying cause (such as infectious, parasitic, rheumatic, thyroid, and hematologic conditions).

Although not recommended for most cases of chronic urticaria, some medical literature suggests that a skin biopsy specimen can provide useful information to rule out urticarial vasculitis when this condition is suspected clinically.[10] Research laboratories can also focus on autoimmune urticaria and detect the presence of anti-FcεRIα autoantibodies, but these tests are neither standardized nor routinely or widely available. Some urticaria specialists assess for such autoantibodies clinically and indirectly through autologous serum skin testing, whereby the patient's serum is centrifuged and used for skin-prick testing in this form of a semiquantitative functional assay for autoimmunity to IgE or IgE receptors bound to cutaneous mast cells. This test is about 75% sensitive and 74% specific for the presence of the autoantibodies.[10]

THERAPEUTIC APPROACH

Regarding conventional management of chronic urticaria, patients often show incomplete responses to antihistamines and are often uncomfortable and frustrated by chronic pruritus. Some cases do respond to systemic corticosteroids, but the potentially serious side effects associated with these medications preclude their safe chronic use.[10] The wide variety of drugs used singly or in combination for this condition is a testament to conventional medicine's inability to fully address and treat the symptoms as well as the underlying causes of urticaria; see Box 211-3 for a complete list of conventional drugs used to treat urticaria.

The basic natural therapeutic approach involves the identification and control of all factors that promote the patient's urticarial response. Obtaining a careful and thorough history is paramount to this process. Acute urticaria is usually a self-limited disease, especially once the eliciting agent has been removed or reduced. Chronic urticaria also responds to the removal of the eliciting agent or agents if they can be identified. In severe anaphylaxis, appropriate emergency care procedures should be followed.

Diet

Although rarely used in conventional medical therapy, even the standard medical literature is beginning to recognize the wisdom of the elimination diet.[10] An elimination or oligoantigenic diet is of utmost importance in the treatment of chronic urticaria (see Chapters 19 and 54). The diet should eliminate not only suspected allergens but also all food additives.

The strictest elimination diets allow only water, lamb, rice, pears, and vegetables. Those foods most commonly associated with inducing urticaria (i.e., milk, eggs, chicken, fruits, nuts, and additives) should definitely be avoided.[66] Foods containing vasoactive amines should be eliminated even if no direct allergy to them is noted. The primary foods to eliminate are cured meat, alcoholic beverages, cheese, chocolate, citrus fruits, and shellfish.

The importance of eliminating food additives cannot be overstated. If food additives do in fact increase the number of perivascular mast cells in the skin, they may also do the same in the small intestine, thereby greatly raising the risk of developing a "leaky gut."

Also of value is control of arachidonic acid–dependent prostaglandins through the use of a diet low in animal fat.

Supplements

- Vitamin C: 1 g three times/day
- Vitamin B_{12}: 1000 mcg intramuscularly per week
- Quercetin: 200 to 400 mg 20 minutes before meals
- Fish oil: 3000 mg EPA+DHA a day

Psychological

The patient should perform relaxation techniques daily. Listening to audio relaxation programs may be an appropriate way to induce the desired state. Appropriate "mind-body" management programs

BOX 211-3 **Drugs Used to Treat Urticaria**

Second-generation histamine$_1$ (H_1) receptor antagonists:
- Cetirizine (Zyrtec)
- Fexofenadine (Allegra D)
- Desloratadine (Clarinex)
- Loratadine (Claritin)

First-generation H_1 receptor antagonists:
- Hydroxyzine (Atarax)
- Diphenhydramine (Benadryl)
- Ranitidine (Zantac)

H_1 and histamine$_2$ (H_2) receptor antagonists:
- Doxepin (Sinequan)—sedation, increased appetite, resultant weight gain
- Cyproheptadine (Periactin)
- Cimetidine (Tagamet)—interference with hepatic microsomal enzymes and androgen receptors

Leukotriene modifiers:
- Montelukast (Singulair)
- Zafirlukast (Accolate)
- 5-Lipoxygenase inhibitors (e.g. Zileuton (Zyflo))
- Nonsteroidal antiinflammatory drugs

Corticosteroid:
- Prednisone

Immunosuppressive treatments:
- Cyclosporin A
- Tacrolimus
- Azathioprine
- Cyclophosphamide
- Mycophenolate mofetil
- Plasmapheresis
- Intravenous immunoglobulin

Others:
- Calcium channel blocker antihypertensives
- Hydroxychloroquine
- Dapsone
- Colchicine
- Methotrexate
- Sulfasalazine
- Intramuscular gold
- Capsaicin
- Impeded androgens
- Warfarin

Data from references 1 and 8.

leading to good clinical outcomes for chronic urticaria is dependent on the clinician's ability to discern unique patient "stories."

Physical Medicine

Daily sunbathing for 15 to 20 minutes or the use of an ultraviolet solarium, especially in chronic physical urticaria, is recommended. Tepid oatmeal baths may also help calm urticarial symptoms, but caution should be exercised with physical modalities when physical triggers such as heat, cold, and water are salient for a particular patient.

Traditional Chinese Medicine/Acupuncture

Acupuncture can work quite well together with naturopathic therapies to treat the causes and symptoms of urticaria.

DIAGNOSTIC SUMMARY

- Most are asymptomatic.
- Symptoms include vague feeling of discomfort, pressure, congestion, bloating, heaviness; can include pain with vaginal sexual activity, urinary frequency, backache, abdominal enlargement, and abnormal bleeding.
- Abnormal bleeding occurs in 30% of women with fibroids.
- Fibroids can undergo degenerative changes with necrosis, resulting in cystic degeneration.
- Calcification can occur.
- Examination by pelvic palpation and/or pelvic ultrasonography.
- The main diagnostic consideration is differentiating a possible fibroid from ovarian malignant tumor, abscess in the fallopian tube/ovarian region, diverticulum from the colon, pelvic kidney, endometriosis, adenomyosis, congenital anomalies, and uterine sarcoma.

GENERAL CONSIDERATIONS

Uterine fibroids are not actually fibrous but consist of muscle, probably both smooth muscle cells and connective tissue. The growth of fibroids is thought to be stimulated by estrogen. The tendency of fibroids to arise during the reproductive years, grow during pregnancy, and regress postmenopausally implicates estrogen as one factor in their cause and growth. Fibroids often demonstrate a growth spurt in the perimenopausal years, likely because of anovulatory cycles with a relative estrogen excess that commonly occurs irregularly during this time.

Uterine fibroids occur in 20% to 25% of women by age 40 and in more than 50% of women overall, with African American women experiencing a higher incidence. Fibroids are the most common indication for major surgery in women and the most common solid tumor in women.

The cause of uterine fibroids remains poorly understood. Increases in local estradiol concentration within the fibroid itself may play a role in its cause and growth. Concentrations of estrogen receptors in fibroid tissue are higher than in the surrounding myometrium but lower than in the endometrium.

Fifty percent to 80% of fibroids do not cause symptoms. Abnormal bleeding, including menorrhagia and metrorrhagia, occurs in 30% of women with fibroids. Other symptoms are pelvic pressure, bloating, congestion, urinary frequency, backache, and pain with vaginal sexual activity. Sometimes the urinary complications may be a cause for concern because they may be due to compression of the ureter, which can then cause hydronephrosis. Fibroids are thought to be the cause of 2% to 10% of cases of infertility. Large fibroids can also interfere with a normal pregnancy by interfering with fetal growth or causing premature rupture of membranes, retained placenta, postpartum hemorrhage, abnormal labor, or an abnormal fetal lie. The incidence of miscarriage due to fibroids is estimated to be two to three times greater than that in women without fibroids.

Fibroids can undergo degenerative changes. One type of degenerative change occurs when the continued growth of the fibroid outpaces the blood supply. A more common type of degenerative change involves a loss of cellular detail as a result of a decrease in the tumor's vascularity. Necrosis leads to cystic degeneration. Calcification can occur over time and is usually seen in postmenopausal women.

DIAGNOSIS

On the basis of mitotic count, nuclear atypia, and other morphologic features, uterine smooth muscle tumors can be classified as leiomyomas, smooth muscle tumors of uncertain malignant potential, and leiomyosarcomas.

A presumptive diagnosis of fibroids can often be made simply with a thorough history and adequate pelvic examination. An enlarged firm uterus or a uterus with irregular edges is the main palpation finding. The diagnostician must distinguish a possible fibroid from an ovarian malignant tumor, fallopian tube or ovarian region abscess, diverticulum, pelvic kidney, endometriosis, congenital anomalies, pelvic adhesions, and a retroperitoneal tumor (rare). Not all of these distinctions can be made with a medical history, physical examination, and pelvic ultrasonography. Submucosal pedunculated fibroids can be visualized with laparoscopy, as can intramural and subserous fibroids.

Uterine fibroids are classified according to their location, as follows:

- Submucosal (just under the endometrium)
- Intramural (within the uterine muscle wall)
- Subserosal (from the outer wall of the uterus)
- Interligamentous (in the cervix between the two layers of the broad ligament)
- Pedunculated (on a stalk, either submucosal or subserous)

THERAPEUTIC CONSIDERATIONS

Natural therapies for uterine fibroids largely involve managing any troublesome symptoms. Women who are seeking an alternative to surgical intervention for uterine fibroids will not find a reliable alternative to shrink their tumors. The following therapies may be able to help to keep a fibroid from growing larger and are usually able to successfully resolve or improve most symptoms related to the tumor. Expectations to reduce the size of fibroids must be low, although there are individual case reports of such results. Reduction in fibroid size due to treatment is difficult to assess, especially in perimenopausal women in their 40s, who at some point will have lower endogenous estrogen production with resultant diminution of the fibroid.

Diet

No dietary approach is known to prevent or shrink uterine fibroids. However, there are very strong rationales for several dietary interventions. For example, a diet high in saturated fats is associated with higher blood levels of estrogen and therefore could have the potential to exacerbate fibroids. Also, low-fiber diets are associated with elevated estrogen levels and poor excretion of estrogen. Dietary change by itself is unlikely to reduce the size of fibroids, but good dietary habits are still important for general health; moreover, they may reduce some of the gastrointestinal symptoms that can be associated with large fibroids or pedunculated fibroids and an enlarged uterus. Clinical observation has demonstrated that natural therapies work best in the context of a healthy lifestyle, including dietary changes. Improving one's diet can help to decrease heavy bleeding or the pain and discomfort caused by the fibroids. In addition to these potential benefits, dietary improvements enhance general well-being.

The tradition of naturopathic medicine holds firmly to the influence of the health of the liver on the health and vitality of an individual. The liver metabolizes estrogen, which can be eliminated from the body by converting it to estrone and finally to estriol, a weaker form of estrogen that has very little ability to stimulate the uterus. Failure of the liver to effectively metabolize estradiol may be one mechanism by which the uterus becomes overestrogenized and responds with fibroid growths.

Saturated fats, sugar, caffeine, alcohol, and "junk foods" are presumably problematic in two main ways. First, they interfere with the body's ability to metabolize estradiol to estrone to estriol. Second, some of them are deficient in B vitamins or interfere with B-vitamin metabolism. If B vitamins are lacking in the diet, the liver will lack some of the raw materials it needs to carry out its metabolic processes and regulate estrogen levels.

Whole grains—such as brown rice, oats, buckwheat, millet, and rye—are excellent sources of B vitamins. Whole grains also help the body excrete estrogens through the bowel. The role of whole-grain fiber in lowering estrogen levels was first reported in 1982.[1] This study found that vegetarian women who eat a high-fiber, low-fat diet have lower blood estrogen levels than omnivorous women with low-fiber diets. Once again, the logic of a high-fiber diet would have implications in preventing and perhaps reducing uterine fibroids because of the stimulating effect of estrogen on fibroid growth.

A high-fiber diet may also help to relieve some of the bloating and congestion sometimes associated with fibroids. Fiber, by bulking up the stool and regulating bowel movements, may relieve some of these symptoms. Some women have a hard time tolerating increased fiber in their diets because their digestive function is otherwise compromised.

Because there is an association between having uterine fibroids and a fourfold increase in the risk of endometrial cancer,[1] three dietary considerations stand out above the others: to increase dietary fiber, lower dietary fat, and increase the intake of soy products and other legumes. A case-control study in a multiethnic population (Japanese, white, Native Hawaiian, Filipino, and Chinese) examined the roles of dietary soy, fiber, and related foods and nutrients as related to the risk of endometrial cancer.[2] A total of 332 women with endometrial cancer were compared with women in the general multiethnic population, and all were interviewed by means of a dietary questionnaire. The researchers found positive associations between a higher level of fat intake and endometrial cancer, between a higher level of fiber intake and a reduction in risk for endometrial cancer, and between a high consumption of soy products and other legumes and a decreased risk of endometrial cancer. Similar reductions in risk were found for a greater consumption of other sources of phytoestrogens, such as whole grains, vegetables, fruits, and seaweeds. The researchers concluded that plant-based diets low in calories from fat, high in fiber, and rich in legumes (especially soybeans), whole-grain foods, vegetables, and fruits reduce the risk of endometrial cancer. These dietary associations may explain at least in part the lower rates of uterine cancer in Asian countries as compared with the United States.

Some have suggested that because soy foods are high in phytoestrogens (specifically isoflavones), which have a weak estrogenic effect, women with uterine fibroids or endometrial cancer should avoid phytoestrogens. This issue deserves some clarification. Soy phytoestrogens do not appear to have an estrogenic effect on the human uterus except in doses higher than 150 mg isoflavones daily in postmenopausal women. They appear to be selective in terms of the tissues on which they have an estrogenic effect and the tissues or organs on which they have an antiestrogenic effect. Soy foods may be analogous to a newer class of drugs called selective estrogen receptor modulators: they act one way in one part of the body and another way in a different part of the body. It seems that in the uterus, soy isoflavones have an antiestrogenic effect.

Nutritional Supplements

Many of the symptoms related to uterine fibroids can be effectively treated with natural therapies. This section presents nutritional supplements that may control or diminish the growth of fibroids. Unfortunately, these recommendations are based more on tradition, theory, logic, and clinical experiences than on scientific evidence.

Lipotropic Factors

Supplements such as inositol and choline exert a lipotropic effect—that is, they promote the removal of fat from the liver. Lipotropic supplements usually are a combination vitamin-and-herbal formulation and sometimes an animal liver extract designed to support the liver's function in removing fat, detoxifying the body's wastes, detoxifying external harmful substances (pesticides, fossil fuels, etc.), and metabolizing and excreting estrogens. These lipotropic products vary in their formulations, depending on the manufacturer, but they are all similar and are intended for the same uses. Many now contain anticancer phytonutrients found in cabbage-family vegetables such indole-3-carbinol (I3C), diindoylmethane (DIM), and sulforaphane. Research has shown that these compounds help to breakdown cancer-causing forms of estrogens to non-toxic forms making them especially important in women with uterine fibroids.[2a,2b]

Pancreatic Enzymes

Supplementation with pancreatic enzymes is usually done to treat pancreatic insufficiency with symptoms of abdominal bloating, gas, indigestion, undigested food in the stool, and malabsorption. The logic for their use in the treatment of uterine fibroids is that the pancreatic enzymes help digest the fibrous/smooth muscle tissue and thus dissolve the fibroids. When used for this purpose, the pancreatic enzyme supplement must be taken between rather than with meals.

Botanical Medicines

Traditional Herbs

Many plants have been used in traditional herbal medicines in an attempt to treat women with uterine fibroids. The plants and herbal formulations described here are used in attempting to reduce uterine fibroids or slow their growth. They have been anecdotally reported to achieve modest success in reducing the size and number of uterine fibroids. There is no scientific research to document the outcomes, but the protocol is presented here as an option.

Scudder's Alterative. Scudder's alterative should be used at 30 to 40 drops in a small amount of warm water three times daily. Its components are as follows:

- Corydalis tubers *(Dicentra canadensis)*
- Black alder bark *(Alnus serrulata)*
- Mayapple root *(Podophyllum peltatum)*
- Figwort flowering herb *(Scrophularia nodosa)*
- Yellow dock root *(Rumex crispus)*

Compounded Echinacea/Red Root.

- Echinacea (*Echinacea* spp.)
- Red root *(Ceanothus americanus)*
- Baptisia root *(Baptisia tinctoria)*
- Thuja leaf *(Thuja occidentalis)*
- Stillingia root *(Stillingia sylvatica)*
- Blue flag root *(Iris versicolor)*
- Prickly ash bark *(Xanthoxylum clava-herculus)*

Compounded Fraxinus/Ceonothus. The constituents of compounded *Fraxinus/Ceonothus* are as follows:

- Mountain ash bark *(Fraxinus americanus)*
- Red root *(Ceanothus americanus)*
- Life root *(Senecio aureus)*
- Mayapple root *(Podophyllum peltatum)*
- Helonias root *(Chamaelirium luteum)*
- Goldenseal root *(Hydrastis canadensis)*
- Lobelia *(Lobelia inflata)*
- Ginger root *(Zingiber officinalis)*

Compounded Gelsemium/Phytolacca. Compounded *Gelsemium/Phytolacca* is also known as the Turska formula. It has the following constituents:

- Gelsemium root *(Gelsemium sempervirens)*
- Poke root *(Phytolacca americana)*
- Aconite *(Aconitum napellus)*
- Bryonia root *(Bryonia dioica)*

Other Herbal Extracts to Consider.

- Chaste tree *(Vitex agnus castus)*
- Nettles *(Urtica dioica)*
- Burdock root *(Arctium lappa)*
- Dandelion root *(Taraxacum officinalis)*
- Oregon grape *(Berberis aquifolium)*
- Crila *(Crinum latifolium)*

Crila has been a part of Vietnamese history and folkore for generations. Numerous benefits of *Crinum* have been reported over the years but none had been clinically studied until recently. Of the 12 varieties of Crila, one specific variety in particular, the *C. latifolium* "Tram," named after the leading researcher, has been studied in women with uterine fibroids. A 3-month study of 195 women with uterine fibroid tumors was conducted in three hospitals in Vietnam in 2007. Crila decreased the size or stopped the growth of the fibroid tumors in 79.5% of the women. In 20.5%, tumor growth continued at a very slow rate. Whereas a heavy menstrual flow was reported by 36% of the women before taking Crila, this had decreased to only 1% after treatment. Side effects reported were slight, including nausea, headache, vaginal dryness, and hot flashes, but these decreased over time.[3]

Topical Applications.

- Poke root oil: Rub onto the belly over the uterus nightly before bed for 1 month then two to three times weekly.
- Castor oil packs: Apply over pelvis three to five times weekly.

Herbal Phytoestrogens

Three types of phytoestrogens are found in medicinal plants: resorcylic acid lactones, steroids and sterols, and phenolics. Phytoestrogens are present in virtually every plant in at least modest levels, with some plants having particularly high levels. Resorcylic acid lactones are not true phytoestrogens because they come from plant mold contamination rather than being synthesized by the plant.

Steroids are the classic steroidal estrogens, estradiol and estrone, which are found in very minute amounts in a few plants such as apple seeds, date palms, and pomegranate seeds in the range of 1 to 10 parts per billion.[4-6] Diosgenin is a steroid derivative found in at least 20 plants, including wild yam species.

Beta-sitosterol is the most common phytosterol and hence is distributed widely throughout the plant kingdom. It is found in plants oils such as wheat germ oil, cottonseed oil, and soybean oil and is the dominant phytosterol found in garlic and onions. Herbal sources include licorice root, saw palmetto, and red clover. Stigmasterol is closely related to beta-sitosterol. Soybean oil is an important source of stigmasterol; it is a better source for laboratory

synthesis of progesterone than beta-sitosterol. Some herbal sources are burdock, fennel, licorice, alfalfa, anise, and sage. The phenolic phytoestrogens are members of the largest single family of plant substances, the flavonoids, which has over 4000 individual members. The term *flavonoid* derives from the Latin *flavus,* meaning "yellow," because the flavonoids are responsible for the yellow, red, white, and blue pigments in plants.

Phenolics include the following substances:

- Isoflavones, which are present in higher concentrations in legumes, especially soybeans, than in any other plants.
- Coumestans, of which coumestrol is the one known estrogenic member. Coumestrol is approximately six times more estrogenic than the isoflavones.[7] Red clover is a medicinal plant with considerable coumestans.
- Lignans, found in high concentrations in grains and cereals and highest in flaxseeds.

There has been some concern and controversy about how phytoestrogens affect the uterus as well as whether, because they have an estrogenic effect, they should be avoided in women with uterine fibroids or endometrial cancer. Research has shown that phytoestrogens actually reduce the incidence of uterine cancer.

Most of the research on the effects of phytoestrogens on the uterus is found in relation to the agriculture industry and the health of grazing animals. In the 1940s, it was reported that the grazing of sheep on red clover in Australia was responsible for their infertility.[8] A Finnish study of pasture legumes identified red clover as containing the highest concentrations of phytoestrogens[9] and showed that abundant intake of red clover resulted in fertility problems in cattle.[10]

In one study on the effects of phytoestrogens in sheep, it was noted that both coumestans and isoflavones produce changes similar to stimulation with steroidal hormones such as estradiol in all of the target organs.[11] Among these changes was an increase in uterine weight. Other investigators have examined the binding of phytoestrogens to the uterus and vagina. Coumestrol has temporarily enhanced the uptake of estradiol by the uterus and vagina only 1 hour after injection into mice.[12] The researchers of this study also noted that coumestrol actually inhibited the uptake of estradiol by the uterus in a prolonged manner; they postulated that there was actually an inhibitory effect at the estradiol receptor sites. Other researchers have observed that coumestans and isoflavones compete with estradiol for uterine receptor sites but have less affinity for them than estradiol does.[13]

Coumestrol has been found to increase uterine weight at a 100-mcg dose when given to rats at a certain time in the development of glands.[14] The estrogenic effect of phytoestrogens appears to be dose-dependent. When given in high enough doses, phytoestrogens have estrogenic effects on all the tissues that are targets of estradiol. Two questions must be answered: What is an excessively high dose and are the observations in animals translatable to humans? One way of answering the first question is to note that countries with a high intake of phytoestrogens (Japan, Thailand, China) do not have increased rates of uterine fibroids.

As in the case of breast cancer, data on women of different cultures support the conclusion that soy phytoestrogens are not an estrogen stimulus for the endometrium. Soy is probably an estrogen antagonist in the uterus, at least at doses of less than 150 mg/day, and it is associated with low rates of endometrial cancer in countries where the intake of soy phytoestrogens is high.[15]

One recent study did raise some concern about high doses of soy phytoestrogens and endometrial effects.[16] A total of 298 women completed a 5-year study of either 150 mg/day of soy isoflavones or placebo tablet. Of the women using 150 mg of soy isoflavones, 70% had an endometrium classified as atrophic, versus 81% of those receiving the placebo. The occurrence of endometrial hyperplasia was higher in the soy group versus the placebo group as well (3.37% vs 0%). There were no endometrial cancers in either group. The estrogenic effect was not detectable at 30 months but only at the end of the 5-year study.

Tripterygium wilfordii Hook F

An uncontrolled but well-designed study looked at the efficacy of a traditional Chinese herbal therapy, *T. wilfordii* Hook F, on uterine fibroids.[17] The researchers used several objective measures for clinical response, including ultrasonographic measurement of fibroid size and determination of blood estradiol, progesterone, testosterone, follicle-stimulating hormone, luteinizing hormone, and prolactin levels by radioimmunoassay. Measurements were taken at baseline and 3 and 6 months. Treatment was effective and time dependent; 28% of fibroids responded in 3 to 4 months and 52% in 5 to 6 months. A total of 25 of the 65 patients were amenorrheic during the course of treatment. Compared with pretreatment values, treatment with *T. wilfordii* induced a rise in mean LH and FSH levels and a decrease in mean estradiol and progesterone levels. The researchers speculated that this result was likely due to a reversible inhibitory effect on the ovaries.

Bioidentical Progesterone

Several older studies have suggested that progesterone may inhibit growth of uterine fibroids. Lipschutz[18] demonstrated that progesterone administered to guinea pigs prevented the formation of tumors that would otherwise be induced by estrogen. In 1946, Goodman[19] reported six cases of clinically diagnosed uterine fibroids that regressed after the use of progesterone therapy. In relation to uterine fibroids, the expression and responsiveness of estrogen and progesterone receptor sites to these hormones is a complex issue.[20]

Lee[21] posited that because uterine fibroids are a result of estrogen stimulation and what he calls "estrogen dominance," the problem is a relative progesterone deficiency and the corrective is to use natural progesterone. He asserted that estrogen dominance is a much greater problem than is recognized by conventional medicine:

Because many women in their mid-thirties begin to have nonovulating cycles, they are producing much less progesterone than expected but still producing normal (or more) estrogen. They retain water and salt, their breasts swell and become fibrocystic, gain weight (especially around the hips and torso), become depressed and lose sex drive; in addition, their bones suffer mineral loss and they develop fibroids. All are signs of estrogen dominance relative to a progesterone deficiency. When sufficient natural progesterone is replaced, fibroid tumors no longer grow in size (they generally decrease in size) and can be kept from growing until menopause, after which they will atrophy. This is the effect of reversing estrogen dominance.

The preferred form of natural progesterone for treating fibroids (unless the patient has heavy bleeding) is a topical cream with about 400 mg of progesterone per one ounce of cream. The cream is to be applied one quarter teaspoon, one to two times daily for 1 week after the menses, and then one quarter to one half teaspoon twice daily for the next 2 weeks (the second half of the menstrual cycle). The progesterone cream is not used for 1 week during the menstrual flow. The cream is applied to the inner arms, chest, inner thighs, and/or palms.

Another theory and counteropinion about the relationship of progesterone to uterine fibroids raises some questions about the use of the hormone in women with fibroids. Rein et al[22] at Brigham and Women's Hospital published a report in 1995 stating not only

that is there no evidence of estrogen directly stimulating myoma growth but also that progesterone and progestins promote the growth of fibroids.[22] The report cites the biochemical, histologic, and clinical evidence supporting an important role for progesterone and progestins in the growth of uterine myomas. This comprehensive hypothesis is based on the analysis of many different technical studies, which according to the reviewers suggests that the development and growth of myomas involve a multistep chain of events.

THERAPEUTIC APPROACH

Diet

The patient should consume a diet low in fat and high in fiber, whole grains, flaxseeds, and soy foods while avoiding saturated fats, sugar, caffeine, and alcohol.

Nutritional Supplements

- Lipotropic factors: 1000 mg of choline and 1000 mg of methionine and/or cysteine a day. Alternatively, S-adenosylmethionine (SAMe) can be used at a dosage of 200 to 400 mg a day.
- Choose one or a combination of the following:
 - Indole-3-carbinol: 300 to 600 mg a day
 - Diindoylmethane (DIM): 100 to 200 mg a day taken with food
- Proteolytic enzymes such as mixed enzyme preparations or pancreatin (8-10× USP): 350 to 750 mg between meals three times/day; or Bromelain: 250 to 750 mg (1800 to 2000 MCU) between meals three times/day

Herbal Medicines

- Echinacea/red root compound: 30 drops in a small amount of warm water three times a day
- *Fraxinus*/*Ceonothus* compound: 30 drops in a small amount of warm water three times a day
- Scudder's alternative: 30 to 40 drops in a small amount of warm water three times a day
- Turska formula: 5 drops in a small amount of warm water three times a day

Topical Treatment

- Bioidentical progesterone cream: one quarter tsp twice a day from day 15 to day 26
- Topical poke root oil over uterus every night for 1 month, then once to three times a week

Conventional Medicine Therapies

Where fibroids cause heavy bleeding, medical management with progestogens or oral contraceptives may be used to manage the bleeding. Some fibroids and uteri are large enough that presurgical treatment with leuprolide acetate (Lupron) may facilitate a less radical surgical option. High-intensity focused ultrasound is a new monmedial technique being used to treat fibroids. In addition, selective progesterone receptor modulators are being investigated as a treatment for fibroid pain and bleeding and for reducing the size of fibroids.

Surgery

Some women will have to consider their surgical options, which are based on the size, number, and location of fibroids, as follows:
- Myomectomy
- Laparoscopic surgery for subserous and pedunculated fibroids
- Uterine embolization
- Hysteroscopic resection of submucous fibroids
- Supracervical hysterectomy (some fibroids may lend themselves to a supracervical laparoscopic hysterectomy)
- Laparoscopy-assisted vaginal hysterectomy

DIAGNOSTIC SUMMARY

- Increased volume of vaginal secretions.
- Abnormal color, consistency, or odor of vaginal secretions.
- Vulvovaginal itching, burning, or irritation.
- Introitus may show patchy erythema, and vaginal mucosa may exhibit congestion, or petechiae.
- Dysuria or dyspareunia may be present.

GENERAL CONSIDERATIONS

Vaginitis, one of the most common reasons for women to seek medical attention, is the most common gynecologic problem encountered by physicians providing primary care to women. It affects all age groups and has a variety of etiologies. An initial vaginitis may be easily diagnosed if the practitioner uses objective tools and easily treated, but recurrent vaginitis can be among the most troublesome and challenging conditions for both practitioners and patients. Early misdiagnosis leads to repeat office visits as well as inappropriate or delayed treatment. Undetected coinfections or an incorrect diagnosis can also have consequences, sometimes serious, especially in pregnant women.

In addition to causing physical discomfort and embarrassment, vaginitis is medically important for several reasons. It may coexist with cervicitis and may be related to a sexually transmitted infection; some of these organisms may be able to ascend and cause pelvic inflammatory disease (PID). PID may in turn lead to tubal scarring, infertility, or ectopic pregnancy. Chronic asymptomatic vaginal infections have been implicated in recurrent urinary tract infections through their action as reservoirs of the infectious agent.[1,2] Some types of vaginal infections, such as bacterial vaginitis (BV) during pregnancy, are associated with preterm delivery, premature rupture of membranes, amnionitis, chorioamnionitis, and postpartum endometritis; if present at delivery, they may be associated with an increased incidence of neonatal infection, with potentially serious or fatal consequences.

The vaginal ecosystem is an environment consisting of an important relationship between normal endogenous microflora, metabolic products of the microflora and the host, estrogen, and the pH level. The normal microflora of a healthy vagina is made up of numerous microorganisms, including *Candida, Lactobacillus* species, gram-negative aerobic bacteria, and facultative organisms *(Mycoplasma* species and *Gardnerella vaginalis)* as well as obligate anaerobic bacteria (primarily *Prevotella, Peptostreptococcus* species, *Eubacterium* species, and *Mobiluncus*). *Lactobacillus* species dominate the healthy vagina of a reproductive-age woman, and although it is difficult to say with certainty which species are most common, molecular biology methods and at least one study have found that *Lactobacillus plantarum, Lactobacillus rheuteri,* and *Lactobacillus acidophilus* are the most often present.[3] Yet another study has found that the most frequent *Lactobacillius* species were *L. crispatus, L. gasseri, L. jensenii,* and *L. rhamnosus*.[4]

The normal microflora of the vagina, dominated by lactobacilli, is capable of inhibiting the adhesion and growth of pathogens; it depletes nutrients available to pathogens and modulates the host immune response and vaginal environment.[5,6] Lactobacilli act via at least three mechanisms: (1) they help to produce lactic acid and other acids as a by-product of glycogen metabolism in the vaginal vault cells and provide a normal vaginal acidic environment of 3.5 to 4.5. Many pathologic microbes

cannot survive or flourish in this pH. (2) Many species of lactobacilli produce hydrogen peroxide, which also inhibits microbial growth. (3) The lactobacilli are competitive with the pathogenic microorganisms for adherence to the vaginal epithelial cells.

TYPES OF VAGINITIS

Vaginitis is commonly classified as being caused by yeast, bacterial vaginosis (BV), *Trichomonas vaginalis,* or atrophic vaginitis. However, these traditional classifications have left gaps in the proper diagnosis and treatment of several atypical scenarios of vaginitis. Experts in this field have proposed three additional categories, which include desquamative vaginitis (DIV), *Mobiluncus* vaginitis and lactobacillosis. Even with the addition of these three categories, there still appear to be two patterns of altered flora in symptomatic women that do not fall into any of the other designated categories. Stuart Fowler of the Mayo Clinic in Scottsdale, Arizona, had proposed two additional categories of altered flora: the first he describes as noninflammatory vaginitis (NV) and the second as inflammatory vaginitis (IV). With the recognition of these two patterns of altered flora, clinical presentations that do not fit the usual criteria for the diagnosis of BV, *Trichomonas, Candida,* atrophic vaginitis, DIV or lactobacillosis can now be recognized and treated. Details regarding these additional types of vaginitis can be found in Fowler's published paper.[7]

Atrophic Vaginitis

Atrophic vaginitis is primarily a problem of perimenopausal and postmenopausal women, although it can also occur in prepubertal girls owing to poorly estrogenized vaginal and vulvar tissue and in postpartum women because of sudden declines in their hormone levels. The vagina undergoes several changes with declining estrogenic stimulation, including a decrease in *Lactobacillus* species in the vagina, a shift to a more alkaline pH, thinning of the vaginal wall, less lubrication, more easily irritated and inflamed tissue, and greater susceptibility to infection. The most commonly reported symptoms are itching or burning and a thin watery discharge, which may occasionally be tinged with blood. (Note that any vaginal bleeding in a postmenopausal woman requires a complete evaluation to rule out endometrial hyperplasia and endometrial carcinoma.) The pH is typically equal to or greater than 5.5, but there is no infection. Other common complaints include dyspareunia and/or vaginal dryness with vaginal sexual activity.

Infectious Vaginitis

More than 90% of vaginitis in reproductive-aged women is caused by BV, candidiasis, or trichomoniasis. BV is the most common of the three. Less common causes of infectious vaginitis include herpes simplex virus, gonorrhea, and *Chlamydia*. Infections of the vulva—including folliculitis, hydradenitis, scabies, condyloma, herpes, syphilis, human papillomavirus and *Candida*—can cause local itching and/or discharge. Rare conditions of the vulva causing itching and/or discharge include chancroid, lymphogranuloma venereum inguinale, and molluscum contagiosum.

Infectious vaginitis (e.g., trichomoniasis) may be sexually transmitted or may arise from a disturbance to the delicate ecology of the healthy vagina (e.g., *Candida* and BV). Vaginal "infections" frequently involve common organisms found in the cervix and vagina of many healthy asymptomatic women.[8]

The unifying factor in the pathogenesis of vaginal infections is not so much a matter of the organisms present in the patient's genital tract but rather of what happens to the patient to make her susceptible to infection.

Factors influencing the vaginal environment are the pH, glycogen content, glucose level, presence of other organisms (particularly lactobacilli), estrogen, semen exposure, nanoxynol-9 spermicide exposure, douching, menstrual blood, and presence of antibodies and other compounds in the vaginal secretions. Many of these factors are, in turn, affected by the woman's internal milieu and general health.

Immune dysfunction may predispose a woman to increased infections, including vaginal infections. Depressed immunity may occur as a result of nutritional deficiencies, medications (e.g., steroids), pregnancy, or serious illness such as HIV. Other medical conditions may predispose a woman to infectious agents, such as diabetes mellitus, hypothyroidism, leukemia, Addison's disease, Cushing's syndrome, and pregnancy.

Predisposing factors for sexually transmitted infections include a higher number of sex partners, unsafe sex, birth control pills, steroids, antibiotics, tight-fitting garments, occlusive materials, douches, chlorinated pools, perfumed toilet paper, and decreased levels of lactobacilli in the vagina. Table 213-1 summarizes the diagnostic differentiation of the most common causes of infectious vaginitis.

Trichomonas vaginalis

Trichomonas vaginalis is a flagellated protozoan slightly larger than a leukocyte. It may be found in the lower urogenital tract of both men and women. Humans appear to be its only host, and sexual transmission appears to be its primary mode of dissemination. *Trichomonas* does not invade tissues and rarely causes serious complications. The most common symptom is leukorrhea associated with itching and burning. The discharge is frequently malodorous, greenish yellow, and frothy. The "strawberry cervix" with punctate hemorrhages is found in only a small percentage of patients with *Trichomonas* infection. Trichomonads grow optimally at a pH of 5.5 to 5.8.[9] Thus, conditions that elevate the pH, such as increased progesterone, will favor overgrowth of *Trichomonas*. Conversely, a vaginal pH of 4.5 in a woman with vaginitis is suggestive of an agent other than *Trichomonas*. A saline wet mount of fresh vaginal fluid demonstrates the presence of small motile organisms to confirm the diagnosis in 80% to 90% of symptomatic carriers.[10,11]

Candida albicans

Both the relative frequency and the total incidence of candidal vaginitis have risen dramatically, 2.5-fold, in the past 20 years. This increase parallels a declining incidence of gonorrhea and trichomoniasis.[12] Several factors have contributed to this increased incidence, chief among them being the greater use of antibiotics. The alterations that antibiotics make in both intestinal and vaginal ecology favor the growth of *Candida*. In the 1970s, Miles et al[11] found a 100% correlation between genital and gastrointestinal *Candida* cultures, leading to the suggestion that significant intestinal colonization with *Candida* may be the single most significant predisposing factor in vulvovaginal candidiasis. However, this suggestion has not been confirmed by adequate research.

Steroids, oral contraceptives, and the continuing rise in incidence of diabetes mellitus all contribute to the problem. *Candida* is 10 to 20 times more common during pregnancy owing to the elevated vaginal pH, increased vaginal epithelial glycogen, elevated blood glucose, and intermittent glycosuria. Yeast infections are three times more prevalent in women wearing pantyhose than those wearing cotton underwear because the pantyhose prevent drying of the area.[13]

TABLE 213-1 **Diagnostic Differentiation of the Common Causes of Infectious Vaginitis**

	CANDIDA	NON-SPECIFIC VAGINITIS	TRICHOMONAS	TRICHOMONAS	HERPES	CHLAMYDIA
Keynote symptoms	Itching	Odor	Odor and itching	Asymptomatic or cervicitis	Vesicles or ulcers	Asymptomatic
Discharge						
pH	<4.5	>4.5	>5.0	<4.5	<4.5	<4.5
Odor	None	Fishy/amines	May be fishy	None	None	None
Appearance	Curdy, adherent, scant to thick	Gray, homogeneous	Greenish, yellow, frothy	Mucopurulent cervicitis	None	None
Pelvic examination	Adherent white patches with an erythematous border	Unremarkable	May show petechial lesions on cervix or vagina mucosa; a "strawberry cervix"	Cervical discharge; may have adenexal tenderness	Small multiple vesicles or ulcers on cervix or vulva	Unremarkable or may show signs of pelvic inflammatory disease
Microscopic examination	Mycelia (10% KOH)	"Clue cells"; few white blood cells (WBCs)	Motile flagellated organisms; few WBCs	Many WBCs with gram-negative intracellular diplococci	Unremarkable	Unremarkable
Culture media	Sauerbaud	Blood culture media	Diamond	Thayer-Martin	Live cell	Live cell or antibody test

A woman who has four or more episodes of vulvovaginal candidiasis within 1 year is classified as having recurrent disease. Many cases of recurrent yeast infections may be caused by non-*albicans* strains of *Candida*. These resistant strains have become more problematic in recent years as women have been using more and more antifungal agents (see Box 213-1). There are three main theories to explain why women have recurring yeast vaginitis: (1) the intestinal reservoir theory, which hypothesizes that a patient's reinoculation is due to *Candida* populating in the gastrointestinal tract and migrating into the vagina; (2) the sexual transmission theory, which points to the possibility that the sex partner is the source of the recurrence; and (3) the vaginal relapse theory, which maintains that some women retain small numbers of yeasts, even after treatment, that later cause a resurgence of symptoms. A considerable body of research supports this last theory.[14,15] These studies include immunologic research suggesting that women with recurrent infections have an abnormal immune response to infection, which leaves them susceptible to further episodes.[16]

The primary symptom of candidal vaginitis is vulvar itching, which can be severe. Burning of the vulva may also be experienced and can be exacerbated by urination or vaginal sexual activity. It is also common to have an increase or change in the consistency of the vaginal discharge. In a classic case, this is associated with the presence of a thick, curdy, or "cottage cheese" discharge that adheres to the vaginal walls. The presence of such a discharge is strong evidence of a yeast infection, but its absence does not rule out *Candida*. Fewer than 20% of symptomatic patients with candidal infection actually display classic thrush patches. Other clues to a candidal etiology are the presence of erythema of the vulva and excoriations due to scratching. The vaginal pH is not usually altered. Neither the character of the discharge nor the symptomatology is sufficient alone to make a diagnosis of *Candida*. A wet mount in saline or 10% KOH should always be performed and the presence of mycelia confirmed. Budding forms of yeast may be found in both normal and symptomatic vaginas, but the mycelial stage is found only in symptomatic women.

BOX 213-1 **Factors Predisposing to Candidal Vaginitis**

- Allergies
- Antibiotics
- Diabetes mellitus
- Elevated vaginal pH
- Gastrointestinal candidiasis
- Oral contraceptives
- Pantyhose
- Pregnancy
- Steroids

Bacterial Vaginosis

The term *bacterial vaginosis* has now been used most often to describe a shift in flora from a predominance of lactobacilli to a predominance of anaerobes and facultative bacteria, which results in a degradation of the mucins that form a natural gel barrier on the vaginal epithelium. This destruction of the mucin layer causes a vaginal discharge characteristic of BV. In addition, destruction of these mucins exposes the cervical epithelium and allows other organisms to affect the cervix, resulting in the appearance of clue cells. The changes on the epithelial surface also cause immunologic shifts. Women with BV have an upregulation of interleukin-1-beta and a decrease in protectant molecules such as secretory leukocyte protease inhibitor.

Three main factors have been identified to explain how the shift from a lactobacilli-dominant environment to one in which the anaerobes and facultative bacteria dominate and therefore why some women experience BV—sexual activity, douching, and the absence of peroxide-producing lactobacilli in the vagina. A new sex partner and frequent sexual activity are associated with an increased incidence of BV. Overall, sexual transmission of BV is not well understood. It may not be truly sexually transmitted but rather may occur by various mechanisms other than the sexual transmission of pathogens. Routine douching is associated with a loss of vaginal

lactobacilli and the occurrence of BV. Women who douche regularly have BV twice as often as women who do not.[17] It is possible that women with an absence of peroxide-producing lactobacilli in the vagina did not have the normal inhabitation of lactobacilli at menarche, or perhaps the lactobacilli were present but were eliminated through the use of broad-spectrum antibiotics.

Other factors have been associated with the development of BV. Cigarette smoking is associated with BV but may be related to the downregulation of the immune response. Racial background has also been associated with BV. Hispanic women are 50% more likely to have BV, and African American women are twice as likely.[18] Although the reasons for these differences are not clear, we do know that African American women practice douching twice as often as white women and that African American women are less likely to have lactobacilli in the vagina.

Examination for BV involves a medical history, observation of the discharge, and determination of vaginal pH. In the woman with symptomatic BV, the vagina has a fishy odor. The characteristic discharge is thin, dark, or dull gray. Itching is not common with BV but may be present if there is a profuse discharge. A whiff test should be performed, and a wet mount test to detect clue cells and observe the vaginal flora. An abundance of various bacteria and the absence or decrease in lactobacilli is consistent with a diagnosis of BV. The numbers of bacteria rise from 100-fold to 1000-fold. For a diagnosis of BV to be made, three of the following four criteria must be met:

- Thin, dark or dull gray, homogeneous, malodorous discharge that adheres to the vaginal walls
- Vaginal pH greater than 4.5
- Positive KOH (whiff/amine) test result
- Presence of clue cells on wet mount microscopic examination

The pH is elevated to 5 to 5.5 in most cases, and there appears to be a correlation between elevated pH and the presence of odor.[19]

When a patient has four or more BV episodes in a year, her underlying problem is most likely an inability to re-establish a normal vaginal ecosystem with the dominant lactobacilli. There is no definition of recurrent BV, but most clinicians would probably agree that more than four episodes in a year would define the disorder. About 30% of women experience a recurrence of symptomatic BV within 1 to 3 months, and about 70% have a recurrence within 9 months.[20] It is not always clear whether the recurrence represents a relapse or a reinfection. Another possibility is that a woman may be asymptomatic at times but, because of the abnormal vaginal ecosystem, she has a chronic underlying condition, so that she is sometimes symptomatic and at other times is not. Women who are asymptomatic yet have no lactobacilli are four times more likely to experience BV. Unfortunately we do not have a proved treatment for asymptomatic women.

There are potential significant consequences of altered vaginal flora in addition to susceptibility to BV. Women with BV and without sufficient lactobacilli are more susceptible to human immunodeficiency virus (HIV) and gonorrhea.[21,22] PID is also associated with BV. There is also now good evidence that the organisms in pregnant women with BV can ascend the genital tract and cause preterm delivery, and such women are more likely to have postpartum endometritis. Women with BV are also at increased risk for infection after gynecologic surgery.

THERAPEUTIC CONSIDERATIONS

Dietary Considerations

The internal milieu of the vagina is a reflection of the condition of the entire body. Vaginal secretions are continuously released that affect and are affected by the microbial flora. These secretions contain water, nutrients, electrolytes, and proteins, such as secretory immunoglobulin (Ig) A. The quantity and character of these components are altered by hormonal and dietary factors. A general healthful diet is recommended in all cases to ensure the availability of all nutrients in sufficient quantity to optimize the body's ability to respond to changing conditions. A well-balanced diet low in fats, sugars, and refined foods is particularly important in vaginitis due to infectious organisms, particularly *Candida.* Patients with depressed immunity are susceptible to higher rates of infection, particularly those due to *Candida, Trichomonas,* and herpes (see Chapter 56 for further discussion of the effects of diet on immune function).

Nutrients particularly important for proper immune function are zinc; vitamins A, C, and E; manganese; and vitamin B complex.

A diet high in lysine-containing foods and low in arginine-containing foods reduces the number and severity of herpetic outbreaks. However, many of the foods that are high in lysine are animal products, which are also high in fats. A low-arginine diet combined with lysine supplements ensures adequate levels of lysine without an excessive intake of fats.

No other food can be considered as specifically medicinal as *Lactobacillus* yogurt. A 1992 study investigated the effects of the daily ingestion of yogurt containing *L. acidophilus* on 33 women with five or more episodes per year of candidal vaginitis. Thirteen women completed the study. The women were randomized into two groups, with the first group receiving 8 oz of *L. acidophilus* yogurt daily for 6 months and then no yogurt for 6 months. The other group consumed the yogurt-free diet for the first 6 months and then the diet including yogurt for the second 6 months. There was a threefold reduction in infections and in candidal colonization during the yogurt diet compared with the non-yogurt diet.[23]

There are also studies that do not support a role for yogurt in the prevention of recurrent candidal vaginitis.[24]

Nutritional Supplements

For general maintenance of health and immune competence, a high-quality multivitamin/multimineral supplement provides low-cost compensation for most dietary inadequacies. In addition, the nutrients discussed here may be useful in one or more types of vaginitis.

Vitamin A and Beta-Carotene

Both vitamin and beta-carotene are necessary for the normal growth and integrity of epithelial tissues, such as the vaginal mucosa. Vitamin A is essential for adequate immune response and resistance to infection. Secretory IgA, a major factor in resistance to infection, is lower in vitamin A–deficient subjects.[25] Beta-carotene is a source of nontoxic vitamin A precursors. In addition, it has been shown to enhance T-cell numbers and to favorably alter their ratios.[26] Excessive vitamin A can be toxic and teratogenic. This is of particular concern in women of reproductive age. Total vitamin A intake should be limited to 5000 IU/day. If larger doses of vitamin A are used, patients should be cautioned to be particularly careful about contraception. Mixed carotenoids rather than synthetic beta-carotene should be used.

B Vitamins

The body requires one or more of the B vitamins for virtually every metabolic activity. B vitamins are needed for carbohydrate metabolism, protein catabolism and synthesis, cell replication,

and immune function. Vitamins B_2 and B_6 have been shown to have estrogen-like effects and to act synergistically with estradiol. Vitamin B_1 and pantothenic acid enhance the action of estradiol, although they have no estrogenic activity themselves.[27] This finding suggests that B vitamins may be of use in estrogen deficiency conditions such as atrophic vaginitis, especially if combined with phytoestrogens.

Vitamin C and Bioflavonoids

Vitamin C and bioflavonoids are essential in any process related to immune function. Deficiency of vitamin C reduces the phagocytic activity of leukocytes. Both vitamin C and bioflavonoids improve connective tissue integrity, thus reducing the spread of infection. Both nutrients are also useful in diminishing the frequency and severity of herpetic outbreaks.[27-32]

Vaginal vitamin C has been used to treat BV. A randomized double-blind placebo-controlled study used a 250-mg tablet of vitamin C inserted vaginally once a day for 6 days.[33] Of the 100 participants, 50 were given the active treatment and 50 placebo. At the end of the study, significantly more patients still had BV in the placebo group (35.7%) compared with the vitamin C tablet group (14%). There were no clue cells in 79% of patients receiving the vitamin C, versus 53% in the placebo group. Bacteria disappeared in 77% of the vitamin C group versus 54% in the placebo group, and lactobacilli reappeared in 79.1% of the vitamin C group versus 53.3% in the placebo group.

Vitamin E

Lack of vitamin E depresses immune response and host resistance. This situation may be corrected by high doses of supplemental vitamin E. Several experiments have shown increased resistance to chlamydial infection when subjects were supplemented with vitamin E. Vitamin E also regulates retinol in humans, and an inadequacy of vitamin E hinders the utilization of vitamin A despite adequate retinol intake.[34] The use of vitamin E for the treatment of atrophic vaginitis has been reported since the 1930s.

Excessive vitamin E intake (>1200 IU/day), however, may be immunosuppressive and may transiently elevate blood pressure. This vitamin is reported to improve glycogen storage and the tone of heart muscle. Thus, extra caution should be exercised in patients with diabetes, hypoglycemia, hypertension, or heart disease. For such high-risk patients, supplementation should begin with a daily dose of 100 IU; with monitoring of blood glucose or blood pressure values, the dose should be increased slowly over time (e.g., by 50 IU/day).

Zinc

All DNA and RNA polymerases and repair and replication enzymes require zinc. Zinc enhances prostaglandin (PG) E_1 synthesis, normalizes lymphocyte activity, and enhances epithelial growth. Low levels of zinc are associated with depressed immunity and thymic atrophy, both of which are correctable when zinc is replenished. Zinc is also essential for the proper utilization of vitamin A. Many otherwise well-nourished adults receive less than 50% of the recommended dietary allowance of zinc from their diets and have one or more measurable signs of zinc deficiency.[35-37]

Treatment with topical and oral zinc has been shown to reduce the duration and severity of herpes outbreaks. This may be due either to the effect of zinc on production of prostaglandins or to the direct antiviral activity of the zinc ion. High levels of zinc are also toxic to *Chlamydia* and *Trichomonas* and have been used successfully in vaginitis that did not respond to antibiotic therapy.[38-42]

Botanical Medicines

Glycyrrhiza glabra

Licorice *(G. glabra)* has antiviral activity against RNA and DNA viruses and has been used successfully in the treatment of herpes. The number and severity of recurrences may be reduced by the repeated application of licorice gel to active lesions.[43] 18-beta glycyrrhetinic acid has been shown in vitro to be effective against *Candida*.[44] (For further discussion, see Chapter 96.)

Chlorophyll

Chlorophyll has bacteriostatic action and soothing actions. Water-soluble chlorophyll may be added to douching solutions for symptomatic relief of vaginitis.[45-47]

Allium sativum

Garlic *(A. sativum)*—which is antibacterial, antiviral, and antifungal—has been shown to be effective even against some antibiotic-resistant organisms.[48-52] The major growth-inhibitory component in garlic extract is allicin; therefore, garlic products with the highest amount of allicin are preferable. Garlic cloves may be carefully peeled so as not to nick them and then pierced with thread and used as tampons. A garlic capsule may also be inserted into the vagina.

Hydrastis canadensis and Berberis vulgaris

Goldenseal *(H. canadensis)* and Oregon grape *(B. vulgaris)* contain berberine, which has a significant effect against many bacteria. Berberine enhances immune function when taken internally as a tea and offers symptomatic local relief when used in douching solutions because it is soothing to inflamed mucous membranes.[53-56] (For further discussion, see Chapter 97).

Melaleuca alternifolia

An alcoholic extract of the oil of the tea tree *(M. alternifolia),* diluted to 1% in water, exerts a strong antibacterial and antifungal action. It was shown in one study to be effective in treating trichomoniasis, candidiasis, and cervicitis. Treatment consists of daily douching combined with saturated tampons used weekly. No adverse reactions were reported, and patients commented favorably on its soothing effect[57] (for further discussion, see Chapter 102). Various tea tree oil preparations have demonstrated antimicrobial activity against *Staphylococcus aureus* and *C. albicans*.[58]

Botanical Mixture

Women with abnormal vaginal discharge who presented to a gynecologic clinic in India were randomly assigned to receive either a cream containing *Azadirachta indica* (neem) seed oil, *Sapindus mukerossi* (reetha) saponin extract, and quinine or placebo. They applied the cream intravaginally at bedtime for 14 days. The results were quite impressive. Symptomatic and microbial assessment showed that 10 of 12 women with *C. trachomatis* vaginitis recovered within 1 week, and 10 of 17 with BV recovered within 2 weeks. No benefit was found in women with candidal or trichomonal infections, and none of the women using the placebo recovered from any of the infections.[59]

Other Agents

Lactobacillus Species

Lactobacilli are the dominant organisms in the vagina of a healthy reproductive-aged premenopausal woman. Properties of these strains—including their adhesiveness, ability to produce acids and hydrogen peroxide, and production of bacteriocidins and

biosurfactants—confer protection on the host. Selection of *Lactobacillus* species and strains for therapeutic purposes with these properties should be a guiding principle for their use in treatment. Substantial data have been published on a number of strains, their properties, and their ability to fight pathogens. Many species and specific strains have demonstrated antipathogenic activity; these include *L. rhamnosus* GG, *L. acidophilus* NCFM, *L. casei Shirota, L. reuteri* MM-53*, L. casei* CRL-431, *L. rhamnosus* GR-1, *L. fermentum* RC-14 (now called *L. rheuteri*), *L. plantarum* 299V, and *L. salivarius.*[60] Other *Lactobacillus* strains, such as *L. johnsonii* LC1, *L. plantarum* 299V, and *L. crispatus* CTV05 also have excellent potential owing to their ability to colonize the vagina and produce hydrogen peroxide, although more data are needed.

Several studies have supported the use of Lactobacillus in the prevention and treatment of vaginitis. One study on treating BV found that both vaginal administration and oral-plus-vaginal administration of lactobacilli were effective at reducing the vaginal pH, treating the current infection, and preventing recurrence over the subsequent 3 months.[61] Another study examined the effectiveness of weekly intravaginal *L. acidophilus* versus clotrimazole (antifungal) tablets in HIV-positive women, a group highly susceptible to recurrent yeast vaginitis, and found the two treatments to be similarly effective at preventing candidiasis.[62] After any conventional treatment with antibiotics, vaginal lactobacilli can be restored by the coadministration of *Lactobacillus* and low-dose vaginal estriol.[63] Another randomized double-blind placebo controlled trial of BV was conducted with 100 women who were given a 2% vaginal clindamycin cream for 7 days and then randomized to receive vaginal capsules for 10 days containing either a placebo or a combination of *L. gasseri* and *L. rhamnosus* (10 billion colony forming units/capsule); this was then repeated for 3 cycles. The probiotics did not improve efficacy of BV treatment during the first month of treatment. However, women initially "cured" were followed for 6 menstrual cycles or until relapse within that time. At the end of 6 months, 64.9% of the probiotic-treated group were still BV-free compared with 46.2% in the placebo group.[85]

Another study enrolled 125 premenopausal women diagnosed with BV by presence of vaginal irritation, discharge and 'fishy' odor, and Nugent criteria and detection of sialidase enzyme. The subjects were treated with oral metronidazole (500 mg) twice daily from days 1 to 7, and randomized to receive oral Lactobacillus rhamnosus GR-1 (1 × 10[9]) and Lactobacillus reuteri RC-14 (1 ×10[9]) or placebo twice daily from days 1 to 30. Primary outcome was cure of BV as determined by normal Nugent score, negative sialidase test, and no symptoms or signs of BV at day 30. A total of 106 subjects returned for 30-day follow-up, of which 88% were cured in the antibiotic/probiotic group compared with 40% in the antibiotic/placebo group (P <0.001). Of the remaining subjects, 30% subjects in the placebo group and none in the probiotic group had BV, while 30% in the placebo and 12% in the probiotic group fell into the intermediate category based upon Nugent score, sialidase result and clinical findings. High counts of *Lactobacillus sp.* (>10[5] CFU/mL) were recovered from the vagina of 96% probiotic-treated subjects compared with 53% controls at day 30. In summary, this study showed efficacious use of lactobacilli and antibiotic in the eradication of BV in black African women.[86]

There are more studies showing these specific species in the treatment of BV. In another clinical trial, 64 premenopausal women with diagnosed BV received a single dose of tinidazole (2 g) and either one capsule of *L. rhamnosus* GR-1 (1 × 10[9]) and *L. reuteri* RC-14 (1 × 10[9]) or placebo orally, twice a day, from days 1 to 28. At day 28, the probiotic group had a higher cure rate (Nugent score and Amsel test) of BV compared with placebo (87.5% vs 50%; P = 0.001). According to the Gram-stain Nugent score, more women in the probiotic group were assessed with "normal" vaginal microbiota compared with placebo (75% vs 34.4%; p = 0.011).[87]

Another way to use these probiotic species is after conventional treatment. In one clinical trial, 95 women (39 with BV, 45 with VVC and 11 had both infections) were randomized to receive a vaginal capsule containing *L. gasseri* LN40, *L. fermentum* LN99, *L. casei rhamnosus* LN113, *P. acidilactici* LN23 (10[8]-10[10] cfu) or placebo for 5 days following conventional treatment. Probiotic strains were present in vaginal cultures 2 to 3 days after administration (53% colonized after one menstruation). Ninety-three percent of women in the probiotic group were cured after 2 to 3 days compared with 83% in the placebo group (78% vs 71% after first menstruation). The probiotic group also had significantly less malodorous discharge.[88]

A clinical trial for vulvovaginal candidiasis employed *Lactobacillus* GG suppositories which were given twice a day for 7 days to women with more than 5 infections per year.[64] Four of the five women with positive yeast cultures had negative cultures after receiving this treatment. All the women reported improvement of their vaginal symptoms of erythema and discharge.

Another study examined the ability of intravaginal *Lactobacillus* to reduce the risk of VVC in 164 HIV-positive women.[65] These women were randomized into three groups with one group receiving *L. acidophilus* intravaginally once a week. The second group received vaginal clotrimazole weekly, and the third group received a placebo. During the 21-month study, the relative risk of developing VVC was 0.5 for the lactobacilli group and 0.4 for the prescription antifungal group compared with placebo. In addition, women who used the lactobacilli went for a longer period of time until they became infected compared with the women who received a placebo.

Other studies have demonstrated that when lactobacilli are given orally, they do colonize the vagina and/or reduce vaginal candidal infections. Three studies, all using *L. rhamnosus* GR-1 and *L. fermentum* RC-14, have been positive and showed a significant reduction in yeast[66] or reduction in the recurrences of yeast vaginitis[67] or restoration of normal vaginal flora in women with a history of VVC.[68]

A review of *Lactobacillus* treatments for VVC in 2003[69] found that vaginally administered or orally ingested *Lactobacillus* is able to colonize the vaginal ecosystem and that supplementation generally had to continue 2 to 6 months in order to sustain continued colonization. The author also concluded that controlled trials are encouraging but few, and that these trials had small numbers of participants, inadequate controls or lack of blinding, high attrition rates, and were not consistent in the form of *Lactobacillus* used. In addition, they produced conflicting results.

There are a few studies that do not support a role for probiotics in the prevention of recurrent VVC or BV.[24,70]

Alone or in combination with other vaginal or oral therapies, selected combination species and strains of *Lactobacillus* can provide the key to establishing normal vaginal microflora, preventing recurring infections, and treating acute candidal and bacterial infections of the vagina.

Iodine

Iodine used topically is effective against a wide range of organisms, including *Trichomonas, Candida, Chlamydia,* and nonspecific vaginitis. Povidone-iodine (Betadine) has all the advantages of iodine without the disadvantages of stinging and staining. A study published in 1969 found povidone-iodine to be effective in treating 100% of cases of candidal vaginitis, 80% of cases due to

Trichomonas, and 93% of combination infections. Although douching has not been as strongly recommended, this study found a douching solution diluted to 1 part iodine in 100 parts water (e.g., 1.5 to 3 teaspoons povidone-iodine to 1 quart of water) used twice daily for 14 days to be effective against most organisms.[69,71-78]

Boric Acid

Boric acid suppositories have been around for a very long time and are both antibacterial and antifungal although its exact mechanism of action is not clear. One hypothesis is the vaginal acidification of boric acid, which then leads to fungal cell wall penetration and disruption of the fungal cell membrane. However, because boric acid's minimum inhibitory concentration works best at a pH similar to a normal uninfected vagina, the hypothesis of increased acidity may not explain its therapeutic effects.

Vaginal capsules of boric acid have been shown to treat candidiasis with success rates equal to or better than those for nystatin. In the most impressive study, 100 women with chronic resistant yeast vaginitis for whom extensive and prolonged conventional therapy had failed were treated with vaginal suppositories containing 600 mg of boric acid twice a day for 2 or 4 weeks. This regimen was effective in curing 98% of the women with failure of response to the most commonly used antifungal agents,[78] thus offering an inexpensive, easily accessible therapy for vaginal yeast infections.[79,80]

A recent review of boric acid for recurrent candida vaginitis sheds some light on its effectiveness.[89] Fourteen studies, including two randomized clinical trials, nine case series, and four case reports were included in this review of the clinical evidence utilizing intravaginal boric acid for vulvovaginal candidiasis. Boric acid was compared with nystatin, gterconazole, flucytosine, itraconazole, clotrimazole, ketoconazole, fluconazole, buconazole, and miconazole. The mycologic and clinical cure rates were as follows:

- Boric acid: varied from 40% to 100%
- Nystatin: 50%
- Terconazole: 70%
- Flucytosine: 90%
- Itraconazole: 90.9%
- Clotrimazole: 36%
- Ketoconazole: 50%
- Fluconazole: 28.6% to 92.3%
- Buconazole: 100%
- Miconazole: 100%

The recurrence rates ranged from 0% to 45.5% in those using boric acid. None of the studies found statistically significant recurrence rates. Vaginal burning sensation was reported in less than 10% of the cases, and watery discharge during treatment and vaginal erythema were reported in seven studies.

Kudzu (Pueraria mirifica)

P. mirifica was examined for its effect on vaginal symptoms, vaginal health index, vaginal pH, and vaginal cytology in postmenopausal women.[81] In this randomized double-blind placebo-controlled study, the participants were given either 20, 30, or 50 mg of *P. mirifica* in capsule or placebo daily for 24 weeks. The average vaginal dryness symptoms in the treatment group decreased after 12 weeks and the maturation index increased after 24 weeks. This effect is evidence of an estrogenic effect on vaginal tissue due to this plant and points to its clinical use for vaginal dryness and dyspareunia due to vaginal atrophy.

Hops

A study was conducted using a combination gel containing phytoestrogens from hops extract, hyaluronic acid, liposomes, and vitamin E.[82] This open noncontrolled trial was performed on 150 postemenopausal women presenting with vaginal dryness and related symptoms. One vaginal suppository per day was inserted for the first 14 days and then one suppository every other day for 14 days. The primary endpoint was the evaluation of vaginal dryness by both the patient and the investigator. The secondary endpoints were the evaluation of other symptoms, including vaginal itching, burning, dyspareunia, inflammation, swelling or irritation, or vulvovaginal abrasions. Among the 130 women who completed the study, the average vaginal dryness scale decreased from 7.92 to 0 by the end of the treatment. Itching disappeared progressively throughout the treatment period and only 4 women still had itching at the end of the treatment. Burning was severe in 92 women at baseline, moderate in 26 and mild in 11. By the end of the treatment, only 4 women complained of mild burning. Dyspareunia also improved progressively; by the end, only 5 women of the 130 who reported mild to moderate or severe dyspareunia had mild dyspareunia. Inflammation and irritation of vulvar and vaginal mucosa also improved significantly from the beginning to the end of the treatment period.

Estrogens

Estrogen therapy is the most effective treatment for moderate to severe atrophic vulvovaginitis. Systemic estrogen therapies and estrogen-progestogen therapies are effective for treating these symptoms. However, when urogenital atrophy is the main or only indication for estrogen, local vaginal estrogen therapy is recommended and not systemic hormone therapy.

Vaginal DHEA

A prospective, randomized, double-blind, placebo-controlled trial evaluated the effect of daily local intravaginal DHEA ovules for 12 weeks in postmenopausal women. The main assessment criteria were sexual dysfunction parameters of libido, arousal, orgasm, and dyspareunia in postmenopausal women with vaginal atrophy.[83] A total of 218 postmenopausal women were randomized to receive a daily ovule of either no DHEA, 3.25 mg DHEA, 6.5 mg DHEA, or 13 mg DHEA. The ovules contained Prasterone, in a lipophilic agent manufactured by Recipharm of Sweden. At 12 weeks, compared with placebo, the 13-mg ovule improved symptoms by 68% in the abbreviated sex function/arousal/sensation domain, in the arousal/lubrication domain by 39%, orgasm by 75%, and dryness during intercourse by 57%. DHEA also fared better than placebo in the desire domain of menopause-specific quality of life inventory by 49% to 23%.

In a related study by the same authors, serum levels of vaginal DHEA showed no or minimal changes during the study period, which lasted up to 12 weeks. All values remained within the normal range of postmenopausal women.[84] This bodes well for safety issues.

DIAGNOSTIC APPROACH

Some women are hesitant to mention symptoms of vaginitis to their doctors out of embarrassment, associating them with poor personal hygiene or promiscuity. Because of the relative frequency of occurrence of vaginitis and the potential for serious consequences if it is untreated, all female patients should be questioned directly regarding the presence of pruritus, vaginal discharge, dysuria, or other symptoms of vaginitis. The following protocol outlines the basic approach to diagnosis:

1. Obtain a complete gynecologic and sexual history, including details of the sexual activity and practices of the patient and her partner or partners. Determine method of contraception, personal hygiene habits, and any self-medications. Rule out the presence of associated symptoms suggestive of PID or systemic infection. Inquire about previous occurrences and their diagnosis, treatment, and resolution.
2. Identification of the causative agent is essential for successful treatment and evaluation. To facilitate diagnosis, the patient should be instructed to avoid douching, intercourse, and vaginal medications for 1 to 2 days prior to the office visit.
3. Determine by speculum examination whether the discharge emanates from the vagina or the cervix. Note the condition of the vaginal mucosa and the character of any discharge. Specimens should be collected and then placed on slides for saline and KOH examination. Use pH paper, amines testing strips, and microscopy of wet mounts.
4. Assess pH.
5. Use microscopy when needed for diagnosis (e.g., KOH wet prep).
6. Appropriate culture specimens should be taken if the diagnosis remains in question or if screening for gonococcus or *Chlamydia* is desired (highly recommended). An abdominal/bimanual examination should be done. A genital culture can be used to diagnose beta strep, yeast, BV (not well), *Staphylococcus aureus*, and *Escherichia coli*. A yeast culture can be ordered and a request to identify different strains of *Candida* can be made. A Group B strep DNA probe or group B strep culture should be ordered for pregnant patients.
7. The Affirm VP III test is used to diagnose *Candida* species, BV, and trichomoniasis.
8. The Thin prep can actually test for many different pathogens including the detection and identification of human papillomavirus and its genotype, HPV 16/18, *Chlamydia*, gonococcus, *Trichomonas*, yeast, *Actinomyces*, herpesviruses I and II, Group B strep, BV, syphilis, *Ureaplasma*, and *Mycoplasma*.

THERAPEUTIC APPROACH

Because approximately 90% of all cases of vaginitis are due to *Candida, Trichomonas,* or *Gardnerella* infections, the following recommendations are primarily directed to treatment of these organisms. Owing to the infectious nature of these organisms, immune support (through proper diet, nutritional supplementation, and botanical medicines) is an important aspect of the therapy. For further recommendations on treating atrophic vaginitis, see Chapter 188; for herpes simplex, see Chapter 172.

Diet

For all causes of vaginitis, a nutrient-dense diet is recommended. All refined foods and simple carbohydrates should be eliminated, and trans fats and saturated fats kept to a minimum. If food allergies are suspected, they should be determined and eliminated.

Supplements

- Vitamin A: 5000 IU/day or beta-carotene 50,000 IU/day
- Vitamin C: 500 to 1000 mg every 4 hours
- B complex: a good balanced B complex averaging 20 to 50 mg of each of the major components
- Zinc: 10 to 15 mg/day
- Vitamin E: 200 IU/day
- *Lactobacillus* species orally and vaginally; dose depends on duration and kind of infection

Botanical Medicines

Hydrastis canadensis (goldenseal)

Dosages three times a day are as follows:
- Dried root or infusion (tea): 2 to 4 g
- Tincture (1:5): 6 to 12 mL (1.5 to 3 tsp)
- Fluid extract (1:1): 2 to 4 mL (0.5 to 1 tsp)
- Solid (powdered dry) extract (4:1 or 8% to 12% alkaloid content): 250 to 500 mg

Allium sativum (garlic): dose equivalent to 4000 mcg allicin.

General Recommendations

1. In treating infectious vaginitis, the following natural medicine concepts should be kept in mind:
 - Remove/limit obstacles to cure
 - Improve vaginal immunity
 - Support systemic immunity
 - Restore vaginal pH
 - Restore vaginal microenvironment
 - Restore gut ecology
 - Decrease inflammation/irritation
 - Provide symptom relief
 - Correct coexisting medical conditions
2. In all cases of chronic vaginitis, *Lactobacillus* capsules or *Lactobacillus* yogurt should be used daily, at least orally if not vaginally, to reinoculate the vagina with these desirable organisms. Oral use should continue for 2 to 6 months to assure colonization.
3. Treatment failures may be due to incorrect diagnosis, reinfection, failure to treat predisposing factors, or patient resistance to the treatment used.
4. *Trichomonas* infections in women require concurrent treatment of the male partner.
5. In cases of recurrent or chronic BV or yeast vaginitis, the clinician should consider treating both male and female partners, infection in whom is a possible explanation for recurrent disease.

Specific Recommendations/Sample Treatments

Acute candidal vaginitis

- 8 oz of *Acidophilus* yogurt every day
- *Lactobacillus* sp. 2 to 10 billion colony-forming units twice a day for 14 days
- Boric acid: 600 mg placed in capsules twice a day for 3 to 7 days

Chronic candida vaginitis

- 8 oz of *Acidophilus* yogurt every day
- *L. species* (e.g., *rhamnosus, rheuteri*) 1-5 billion; twice daily for 1 to 6 months
- Boric acid: 600 mg vaginal suppositories twice a day for 2 weeks (4 weeks if patient is not free of symptoms and wet mount examination still shows organisms at 2 weeks)
- To prevent vulvar irritation from the boric acid dispensed from the dissolved capsule, vitamin E oil or petroleum jelly can be applied to the external genitalia.

Bacterial vaginosis

- Vitamin C vaginal tablet for 6 days and then boric acid suppositories once a day for 1 week

- Multiple *Lactobacillus* species/strains 2 billion or more a day for 2 weeks
- Systemic immune support

Trichomonas

- Povidone-iodine: applied twice a day
- Zinc sulfate: applied a day
- *M. alternifolia* oil: applied a day

Atrophic Vaginitis

- Intravaginal Estriol cream, 1 mg/g. Insert 1 g a day for 2 weeks, then 1 g twice a week as maintenance. Other vaginal estrogen options: vaginal estradiol 0.1% cream, Premarin cream, Estring, Vagifem.
- Consider vaginal DHEA ovules 13 mg/day for 12 weeks, then twice a week.

DIAGNOSTIC SUMMARY

- Dilated, tortuous superficial veins in the lower extremities.
- May be asymptomatic or associated with fatigue, aching discomfort, feeling of heaviness, or pain.
- Edema, pigmentation, and ulceration of the skin of the distal leg may develop.
- Women are affected four times as frequently as men.

GENERAL DISCUSSION

Veins are fairly frail structures. Defects in the wall of a vein lead to dilation of the vein and damage to the valves. When the valves become damaged, the higher static pressure results in the bulging veins known as *varicose veins*.

Varicose veins affect nearly 50% of middle-aged adults. The subcutaneous veins of the legs are the veins most commonly affected, owing to the gravitational pressure that standing exerts on them. When an individual stands for long periods, the pressure buildup in the vein can increase up to 10 times. Hence, individuals with occupations that require long periods of standing are at greatest risk for the development of varicose veins.

Women are affected about four times as frequently as men; obese individuals have a much greater risk; and the risk rises with age owing to loss of tissue tone, loss of muscle mass, and weakening of the walls of the veins. Pregnancy, which increases venous pressure in the legs, may also lead to the development of varicose veins.

In general, varicose veins pose little risk if the involved vein is near the surface. These types of varicose veins are, however, cosmetically unappealing. Although significant symptoms are not common, the legs may feel heavy, tight, and tired. If the varicose veins are associated with significant chronic venous insufficiency, leg ulcers may form that are often difficult to resolve.

A more serious form of varicose vein involves obstruction and valve defects of the deeper veins of the leg. This type of varicose vein can lead to problems such as thrombophlebitis, pulmonary embolism, myocardial infarction, and stroke. Phlebography and Doppler ultrasonography are the most accurate methods of diagnosing deep venous involvement.

ETIOLOGY

The following theories have been advanced to explain the cause of varicose veins:

- Genetic or functional weakness of the veins or venous valves.
- Excessive venous pressure due to increased straining during defecation, often caused by a low-fiber diet.
- Long periods of standing and/or heavy lifting.
- Damage to the veins or venous valves secondary to thrombophlebitis.

The major cause of varicose veins is weakness of the vascular walls due to either abnormalities in the proteoglycans of the interendothelial cement substance or excessive expression/activity/release of matrix metalloproteinases (MMPs) such as β-*N*-acetylglucosaminidase, β-glucuronidase, and arylsulfatase, which degrade extracellular matrix proteins and affect the structural integrity of the vein wall, leading to increased capillary permeability and loss of venous structural integrity. The MMPs also affect the endothelium and smooth muscle components of the vein wall, thereby causing changes in the properties of venous constriction/relaxation.

Endothelial cell injury also triggers leukocyte infiltration, activation, and inflammation, which leads to further damage to the vein wall and thus chronic and progressive venous insufficiency and varicose vein formation.[1,2]

THERAPEUTIC CONSIDERATIONS

The treatment of varicose veins ranges from conservative measures to surgical interventions. Conservative therapy involves the following:

- Elevating the legs periodically.
- Wearing graduated compression stockings with variable pressure gradients, especially if standing for long periods of time is unavoidable.
- Exercise, especially walking, riding a bike, or jogging, is thought to be helpful, because contraction of the leg muscles pushes pooled blood back into circulation.
- Achieving or maintaining one's ideal body weight.
- Maintaining adequate intake of dietary fiber to avoid increasing venous pressure consequent to straining during defecation.
- Using nutritional and botanical agents to assist in improving the structural integrity of the veins.

For severely affected veins, more aggressive treatment may be necessary. The traditional surgical treatment has been vein stripping to remove the affected veins. Newer, less invasive treatments that seal the main leaking vein at the highest point of valvular dysfunction on the thigh include ultrasound-guided foam sclerotherapy, radiofrequency ablation, and endovenous laser treatment. Because most of the blood in the legs is returned by the deep veins, the superficial veins, which return only about 10% of the total blood of the legs, can usually be removed or ablated without serious harm. Sclerotherapy with segmental phlebectomy (stripping of the vein) is also popular. In sclerotherapy with segmental phlebectomy, a sclerosing agent is injected at the highest portion of the affected vein. Only the most badly diseased segments of vein are stripped away with segmental phlebectomy.

Dietary Factors

Fiber

A low-fiber diet that is high in refined foods contributes to the development of varicose veins.[3,4] Individuals consuming a low-fiber diet tend to strain more during bowel movements because their smaller and harder stools are more difficult to pass. This straining raises the pressure in the abdomen, obstructing the flow of blood up the legs. Over time, this increased pressure may significantly weaken the vein walls, leading to the formation of varicose veins or hemorrhoids, or it may weaken the wall of the large intestine and produce diverticuli.[5]

A diet rich in vegetables, fruits, legumes, and grains promotes peristalsis, and many fiber components attract water and form a gelatinous mass, which keeps the feces soft, bulky, and easy to pass. The net effect of a high-fiber diet is significantly less straining during defecation.

Natural bulking compounds can also be used. These substances, particularly psyllium seed, pectin, and guar gum, possess a mild laxative action owing to their ability to attract water and form a gelatinous mass. This process, as previously mentioned, keeps the feces soft and promotes peristalsis, significantly reducing straining during defecation. These types of fibers are generally less irritating than wheat bran and other cellulose fiber products.

Flavonoid-Rich Berries

Berries, such as hawthorn berries, cherries, blueberries, and blackberries appear to be beneficial in the prevention and treatment of varicose veins. These berries are very rich sources of proanthocyanidins and anthocyanidins,[6-8] flavonoids are noted for their ability to improve the integrity of ground substance and the vascular system. Extracts of several of these berries are used widely in Europe for various circulatory conditions.[6-8]

Another rich source of flavonoids is buckwheat, which is high in rutin. In one double-blind placebo-controlled study, 77 patients with chronic venous insufficiency were given placebo tea or *Fagopyrum esculentum* (buckwheat) tea for 12 weeks. The tea was standardized to contain 5% total flavonoids, yielding a daily dosage of 270 mg of rutin. A statistically significant reduction in total leg volume was seen in the treated group, along with statistically insignificant improvements in capillary permeability and symptoms. No adverse effects were noted.[9]

The efficacy of these extracts is related to their ability to accomplish the following[6-8]:

- Reduce capillary fragility
- Increase the integrity of the venous wall
- Inhibit the breakdown of the compounds composing the ground substance
- Improve the muscular tone of the vein

Consumption of these berries or of their extracts or other flavonoid-rich extract like grape seed or pine bark (see Chapter 117) is indicated for individuals with varicose veins as well as those who wish to prevent them.

Botanical Medicines

Horse chestnut *(Aesculus hippocastanum)* was once native to western Asia but has been widely distributed all over the world because of its beauty. In addition to enhancing the appearance of city streets and parks, this hearty tree possesses significant medicinal effects. In particular, the seeds of the horse chestnut tree have been valued for centuries for their ability to improve hemorrhoids and varicose veins.[10] This historical use, seemingly successful, ultimately has led to the development of topical and oral preparations with confirmed clinical benefits for these same conditions.[11,12]

The chief component of horse chestnut seed extract (HCSE) is escin, a triterpenic saponin, although other molecules such as proanthocyanidin A_2 and esculin also exert significant effects.[11] These horse chestnut compounds have shown a number of pharmacologic effects beneficial in the treatment of chronic venous insufficiency. First, all three active components have been shown to exert significant vasoprotective and venotonic effects, such as antioxidant effects, combined with an ability to inhibit enzymes that destroy venous structures, such as collagenase, hyaluronidase, β-glucuronidase, and elastase, thus shifting the equilibrium between degradation and synthesis of proteoglycans and other critical venous structures toward a net synthesis. In addition, HCSE prevents the accumulation of leukocytes in varicose vein–affected limbs and their subsequent activation, an important pathophysiologic mechanism in varicose veins. It appears that the ultimate effect of HCSE treatment is the prevention of vascular leakage along with an increase in the tone of the vein itself.[13]

The therapeutic benefits of HCSE has been confirmed in more than 16 double-blind clinical trials demonstrating a positive effect in the treatment of varicose veins and thrombophlebitis.[11] In fact, extracts of HCSE standardized for escin appear to be as effective as compression stockings, but without the nuisance. For example, in a well-designed study, the effectiveness of HCSE versus compression stockings was examined in 240 patients with varicose veins.[14] Patients received either HCSE (50 mg/day of escin), compression stockings, or a placebo for 12 weeks. Effectiveness was evaluated

by a phlethysmograph—a machine that measures the volume of fluid in the leg. After the 12-week trial, lower-leg volume of the more severely affected leg decreased an average of 56.5 mL with compression therapy and 53.6 mL with HCSE, whereas it rose by 9.8 mL with the placebo.

In the treatment of varicose veins, escin can be given orally as well as topically. The topical formula is also of benefit in the treatment of bruises, owing to escin's ability to reduce capillary fragility and swelling.

Centella asiatica

When given orally, an extract of *C. asiatica* containing 70% triterpenic acids (asiatic acid, madecassic acid, and asiatoside) has demonstrated impressive clinical results in the treatment of cellulite, venous insufficiency of the lower limbs, and varicose veins (see Chapter 75 for more information).[15-19]

Several experimental studies have discovered that *Centella* exerts a normalizing effect on the metabolism of connective tissue. Specifically, it possesses an ability to enhance connective tissue integrity by stimulating glycosaminoglycan synthesis without promoting excessive collagen synthesis or cell growth.[16] Glycosaminoglycans are the major components of the amorphous intercellular matrix (ground substance), in which collagen fibers are embedded. The net outcome of *Centella*'s effect on connective tissue is the development of normal tissue.

The effect of *Centella* in venous insufficiency and varicose veins appears to be related to its ability to enhance connective tissue structure, reduce sclerosis, and improve blood flow through the affected limbs.[15-19] (For further information, see Chapter 75.)

Ruscus aculeatus (Butcher's Broom)

The shrub butcher's broom (*Ruscus aculeatus*) is a member of the lily family that grows in the Mediterranean region. The rhizome from butcher's broom has a long history of use in treating venous disorders such as hemorrhoids and varicose veins. This historical effect has been confirmed in experimental and double-blind studies in patients with varicose veins.[20-22] The active ingredients in butcher's broom are ruscogenins. These compounds have demonstrated a wide range of pharmacologic actions, including anti-inflammatory and vasoconstrictor effects. In Europe, butcher's broom extracts are used extensively, both internally and externally, in the treatment of varicose veins and hemorrhoids. Double-blind clinical studies have shown that these preparations offer benefits in terms of both symptomatic relief and improved venous blood flow.[20-22]

Flavonoids and Flavonoid-Rich Extracts

As mentioned above, flavonoids and flavonoid-rich extracts are useful in the prevention and treatment of varicose veins. The most useful single flavonoid for varicose veins may be micronized diosmin. Micronization involves a high-technology grinding process with a jet of air at supersonic velocities, reducing the size of standard particles from more than 20 to less than 2 micrometers. As a result, there is better and faster absorption and thus an increased bioavailability, which lends greater clinical efficacy. In addition to showing considerable improvements in signs and symptoms, purified micronized diosmin decreases the levels of some plasma markers of endothelial activation, including soluble endothelial adhesion molecules.[23] Micronized diosmin has also shown considerable benefits in promoting the healing of venous ulcers and hemorrhoids.[24] For more information, see Chapter 92.

Bromelain and Other Fibrinolytic Compounds

Individuals with varicose veins have a decreased ability to break down fibrin.[25] This fact is extremely important because fibrin is deposited in the tissue near the varicose veins. The skin then becomes hard and "lumpy" owing to the presence of the fibrin and fat (lipodermatosclerosis). In addition, decreased fibrinolytic activity raises the risk of thrombus formation, which may result in thrombophlebitis, myocardial infarction, pulmonary embolism, or stroke.

Herbs that increase the fibrinolytic activity of the blood are therefore indicated. Capsicum (cayenne),[26] garlic,[27] onion,[28] and ginger[29] all promote fibrin breakdown. Liberal consumption of these spices in foods is recommended for individuals with varicose veins and other disorders of the cardiovascular system.

The proteolytic enzyme from pineapple, bromelain, also appears to be indicated in the treatment of varicose veins. Vein walls are an important source of plasminogen activator, which promotes the breakdown of fibrin. Veins that have become varicosed have decreased levels of plasminogen activator. Bromelain acts in a similar manner to plasminogen activator to cause fibrin breakdown.[30] Bromelain may help prevent the development of the hard and lumpy skin found around varicosed veins.

THERAPEUTIC APPROACH

Conservative therapy as described above should be employed as early as possible in patients with varicose veins. It may halt the progression and prevent further need for more aggressive therapy.

Diet

A diet rich in dietary fiber is indicated. The diet should contain liberal amounts of proanthocyanidin- and anthocyanidin-rich foods, such as blackberries, cherries, and blueberries. Garlic, onions, ginger, and cayenne should also be consumed liberally.

Botanical Medicines

Choose one or more of the following:

- *A. hippocastanum*: bark of root, 500 mg three times a day
- Escin: 50 mg two or three times a day; alternatively, escin preparations may be applied topically in a 1% concentration
- *C. asiatica* extract (70% triterpenic acid content): 30 mg three times a day
- *R. aculeatus* extract (9% to 11% ruscogenin content): 100 mg three times a day
- Grape seed (*Vitis vinifera*) extract (95% procyanidolic oligomers): 150 to 300 mg/day
- Pine bark extract (*Pinus pinaster*): 150 to 300 mg/day
- Micronized diosmin: 500 to 1000 mg/day
- Hydroxyethyrutosides: 1000 to 3000 mg/day

The following may be useful as an adjunct:

- Bromelain (minimum 1500 MCU): 500 to 750 mg three times a day between meals

APPENDIX 1 | Candida Questionnaire*

PURPOSE

The purpose of this questionnaire is to estimate the likelihood of having an overgrowth of intestinal yeast.

QUESTIONNAIRE

History

	Point score
1. Have you taken antibiotics for acne for 1 month or longer?	25
2. Have you, at any time in your life, taken other "broad-spectrum" antibiotics for respiratory, urinary, or other infections for 2 months or longer, or in short courses four or more times in a 1-year period?	20
3. Have you ever taken a broad-spectrum antibiotic (even a single course)?	6
4. Have you, at any time in your life, been bothered by persistent prostatitis, vaginitis, or other problems affecting your reproductive organs?	25
5. Have you been pregnant?	
One time	3
Two or more times	5
6. Have you taken birth control pills?	
For 6 months to 2 years	8
For more than 2 years	15
7. Have you taken prednisone or other cortisone-type drugs?	
For 2 weeks or less	6
For more than 2 weeks	15
8. Does exposure to perfumes, insecticides, fabric shop odors, and other chemicals provoke:	
Mild symptoms	5
Moderate to severe symptoms	20
9. Are your symptoms worse on damp, muggy days or in moldy places?	20
10. Have you had athlete's foot, ringworm, "jock itch," or other chronic infections of the skin or nails?	
Mild to moderate	10
Severe or persistent	20
11. Do you crave sugar?	10
12. Do you crave breads?	10
13. Do you crave alcoholic beverages?	10
14. Does tobacco smoke really bother you?	10
Total score for this section	___

Major Symptoms

For each of your symptoms, enter the appropriate number in the "point score" column:

- If a symptom is occasional or mild, score 3 points.
- If a symptom is frequent or moderately severe, or both, score 6 points.
- If a symptom is severe or disabling, or both, score 9 points.

	Point score
1. Fatigue or lethargy	___
2. Feeling of being "drained"	___
3. Poor memory	___
4. Feeling "spacey" or "unreal"	___
5. Depression	___
6. Numbness, burning, or tingling	___
7. Muscle aches	___
8. Muscle weakness or paralysis	___
9. Pain and/or swelling in joints	___
10. Abdominal pain	___
11. Constipation	___
12. Diarrhea	___
13. Bloating	___
14. Persistent vaginal itch	___
15. Persistent vaginal burning	___
16. Prostatitis	___
17. Impotence	___
18. Loss of sexual desire	___
19. Endometriosis	___
20. Cramps or other menstrual irregularities, or both	___
21. Premenstrual tension	___
22. Spots in front of eyes	___
23. Erratic vision	___
Total score for this section	___

Other Symptoms

For each of your symptoms, enter the appropriate figure in the "point score" column:

- If a symptom is occasional or mild, score 1 point.
- If a symptom is frequent or moderately severe, or both, score 2 points.
- If a symptom is severe or disabling, or both, score 3 points.

TABLE A1-1 **Interpretation**

YEAST-CONNECTED HEALTH PROBLEMS	WOMEN	MEN
Almost certainly present	>180	>140
Probably present	120-180	90-140
Possibly present	60-119	40-89
Less likely present	<60	<40

APPENDIX 2

Cervical Escharotic Treatment Instructions: For the Practitioner

Tori Hudson, ND

1. Before beginning the treatment, prepare the following items:
 a. Zinc/chloride ($ZnCl_2$)/Sanguinaria solution (90 g $ZnCl_2$/60 mL sterilized water; made at a compounding pharmacy). Take ¼ tsp $ZnCl_2$ solution and place in empty cup. Add ¾ tsp Sanguinaria tincture to this same cup. This will now be the mixture used for one treatment.
 b. One cup distilled water.
 c. ⅓ cup calendula succus.
 d. A cup containing two powdered bromelain capsules or tablets
2. Insert speculum and visualize the cervix.
3. Blot the cervix dry with large cotton swab or cotton ball on the end of a ring forceps.
4. Dip a large cotton swab into the distilled water and then squeeze out the water with your fingers. Place the damp swab into the bromelain and attempt to thickly cover the face of the cervix with the powder. This will have to be repeated two to four times to cover properly. The same step must be done in the endocervical canal with a small cotton tip applicator; i.e., dampen it, place in the bromelain, and apply to endocervix one to three times. Use a new cotton tip applicator each time.
5. Leave the bromelain on the cervix and in the endocervical canal for 15 minutes. A gynecologic lamp should be placed facing the vagina so that gentle heat is provided during this portion of the treatment.
6. Now remove the bromelain by placing a large cotton swab in the calendula succus and then applying it to the cervix, thus washing off the bromelain. This must also be done with a small cotton tip applicator to the endocervical canal. Be liberal; repeat two to four times. Take a dry large swab and absorb the washings that have pooled in the vagina.
7. Now soak a large swab in the $ZnCl_2$/Sanguinaria mixture prepared earlier. Apply this to the cervix once. Repeat this procedure with a small cotton tip applicator and insert in the endocervical canal. Leave on for one minute. If this causes pain, wash the cervix with a small amount of distilled water. Avoid contact of the $ZnCl_2$/Sanguinaria mixture with the vaginal wall.
8. Wash off the $ZnCl_2$/Sanguinaria mixture with swabs of calendula succus. Wash the endocervical canal as well with a cotton tip applicator. Absorb the liquid that has pooled in the vagina with a dry cotton swab.
9. Insert two "Vag Pack" suppositories (See Appendix 12, "Vaginal Depletion Pack"). Using forceps or other appropriate instruments, attempt to have the suppositories lie lengthwise across the cervix. Instruct the patient to leave the suppositories in place for 24 hours (using a small sanitary napkin due to leakage).
10. After the last escharotic treatment:
 Week 1: Vitamin A suppository every night for 6 nights
 Week 2: Herbal vaginal suppository every night (herbal suppository: myrrh, echinacea, slippery elm, golden seal root, marshmallow root, geranium, and yarrow) for 6 nights or alternate suppository (vitamin A, thuja, lomatium isolate, green tea)
 Week 3: Vitamin A suppository every night for 6 nights
 Week 4: Herbal vaginal or alternate suppository every night for 6 nights

Note: The Escharotic Treatment is best done twice a week with two full days between treatments.

APPENDIX 3 | Crohn's Disease Activity Index

Patient name: _____ Chart #: _____

Date: _____

		Day 1 2 3 4 5 6 7	Sum	×	Factor	=	Subtotal
X_1	Number of liquid or very soft stools	\| \| \| \| \| \| \|	___	×	2	=	_____
X_2	Abdominal pain (0 = none, 1 = mild, 2 = moderate, 3 = severe)	\| \| \| \| \| \| \|	___	×	5	=	_____
X_3	General well-being (0 = well, 1 = slightly under par, 2 = poor, 3 = very poor, 4 = terrible)	\| \| \| \| \| \| \|	___	×	7	=	_____
X_4	Number of six listed categories the patient now has: 1. Arthritis/arthralgia 2. Iritis/uveitis 3. Erythema nodosum/pyoderma gangrenosum/ aphthous stomatitis 4. Anal fissure, fistula, or abscess 5. Other fistula 6. Fever higher than 100° F during past week		___	×	20	=	_____
X_5	Taking Lomotil/opiates for diarrhea (0 = no, 1 = yes)		___	×	30	=	_____
X_6	Abdominal mass (0 = none, 2 = questionable, 5 = definite)		___	×	10	=	_____
X_7	Hematocrit (HCT):___ (standard: males = 47, females = 42)	Standard – HCT (add or subtract according to sign)		×	6	=	_____

APPENDIX 4

Fasting—Patient Guidelines

Alan Goldhamer, DC, Stephen Helms, NMD, and Trevor K. Salloum, BA, ND

WHY FAST?

Fasting is one of the quickest ways to increase elimination of wastes and to enhance the reparative processes of the body. Fasting has been practiced throughout history and is universally employed in the animal kingdom.

Scientific inquiry into fasting began in the early 1900s. Research found it to be useful in the treatment of the following:

- Diabetes
- Epilepsy
- Obesity
- Psychological illnesses
- Arthritis
- Heart disease
- Skin disease
- Toxic poisoning

Loss of minerals or vitamins is usually not a concern during a short fast; humans have effective biochemical mechanisms for adapting to long periods without food.

The short fast (3 to 5 days) is a good chance for the body to acquire optimal rest, both mental and physical. This is an opportunity to build health, break old habits, and increase awareness of oneself. Although longer fasts are required in chronic disease, the short fast can be conducted at home, rather than in an inpatient facility.

The ideal time to begin a fast is when hunger disappears or at the first sign of an illness. Although a short fast can be implemented at any time, it is better to begin on a weekend or during a time when you can be inactive. The more rest, the better the results: energy can be directed toward healing instead of other body functions.

Before embarking on a fast, check with your physician. If you are on any medications (including herbs and nutritional supplements) or have any chronic disease, slight alterations may be necessary. A physical examination is important before a fast to ensure there are no contraindications and to allow your physician to monitor your progress more effectively.

A positive mental outlook is important. The benefits of fasting include:

- Decreased weight
- Clearer skin
- Increased elimination of toxins
- Tissue repair
- Decreased pain and inflammation
- Increased concentration
- Relaxation and spare time
- Savings in food costs

Perhaps the greatest benefit is the satisfaction that you are taking a major role in improving your health.

FASTING DIRECTIONS

Starting Your Fast

Prepare for your fast on the day before you stop eating by making your last meal one of only fresh fruits and vegetables (some authorities recommend a full day of raw food to start a fast). In addition, finish all last-minute errands so that you can establish an environment as free of stress and responsibility as possible.

During the Fast

Only water—distilled or spring water is best—should be taken by mouth while fasting. (Some authorities recommend fruit or vegetable juice, but this is actually an elimination diet rather than a fast.) The quantity of water should be dictated by thirst, but drink at least a few glasses every day.

Take no coffee, tea, juice, soft drinks, cigarettes, or anything else by mouth except water. If possible, avoid the smell and sight of food. If you have to prepare food for other family members, satisfy your senses with the aroma—no sampling!

Try to keep your mind away from food by reading a book (especially a book on fasting), listening to music, writing a letter, watching a movie, taking a leisurely walk in a park, driving to a pleasant destination, etc.

Exercise is not usually encouraged while fasting. You want to conserve fuel and allow maximal healing. Short walks and light stretching are useful, but heavy workouts tax the system and inhibit repair and elimination.

Cleansing the skin with lukewarm water is encouraged, but extremes of temperature can be tiring. Try to avoid deodorants, soaps, sprays, detergents, synthetic shampoos, and exposure to other chemicals. These only hinder elimination and add to the body's detoxification and elimination burden.

Sunlight is essential for healthy cells, but excessive exposure will strain the body's protective systems. Try to obtain at least 10 to 20 minutes of direct sun exposure per day. Many fasting institutions have solariums in which guests sunbathe.

Rest is one of the most important aspects of the fast. Try to take a nap or two during the day. You will probably require less sleep at night because your daily activity has decreased.

Enemas are not usually necessary, but this will depend on your individual health. If you are worried about constipation, a longer pre-fast period of fresh fruits and vegetables will assist elimination.

Body temperature usually drops during a fast, as do blood pressure and pulse and respiratory rates—all measures of the slowing metabolic rate of the body. Therefore, it is important to stay warm. If needed, you may use a hot water bottle at night.

Breaking Your Fast

Breaking your fast is a good time for you to consider carefully what you are eating and why. While breaking your fast, as outlined in Table A4-1, and in the days that follow, it can be helpful to you and your physician to carefully record what you eat and how you feel after eating. Many of today's health problems are due to food allergies and overeating. Take this time to choose which eating habits you truly want to establish. As you break your fast, eat slowly, chew thoroughly, limit quantities, eat foods at room temperature, and enjoy!

TABLE A4-1 **Breaking Your Fast**

BREAKFAST	LUNCH	DINNER
Day 1: One of the following: ½ melon ½ nectarine ½ pineapple	A different fruit from the breakfast list	8 oz of any fruit
Day 2: 12 oz of one type of fresh fruit	14 oz of whole pears, papaya, or citrus fruit	Raw vegetable salad with leafy greens, tomato, celery, and cucumber or 2 pears, 2 apples, and an avocado
Day 3: Resume healthy diet—raw fresh fruits, raw/steamed vegetables, whole grains, nuts, seeds, and legumes		

If You Have Problems

Most discomfort during fasting is usually brief as the body works quickly to restore homeostasis. You may experience headaches, dizziness, nausea, coated tongue, bad odor, mild palpitations, and mucous discharge. If your symptoms are intolerable and persist, notify your physician or break your fast with an orange and resume fasting when symptoms disappear.

SUMMARY

Importantly, although fasting is an effective way to improve your health, it is only one part of a total health-building program, not a panacea. Fresh air, rest, exercise, sunshine, pure food and water, emotional health, and wholesome foods eaten in appropriate quantities are equally important in building and maintaining health.

APPENDIX 5 | Gluten and Gliadin Content of Select Foods

FOOD	TOTAL PROTEIN	PROLAMINES* (% OF TOTAL PROTEIN)	GLIADIN (MG/100 G)	GLUTELINS† (% OF TOTAL PROTEIN)	CROSS-REACTIVITY WITH GLIADIN
Wheat	10-15	40-50	6900	30-40	++++

*Primarily gliadin.

†Primarily gluten.

APPENDIX 6

Glycemic Index, Carbohydrate Content, and Glycemic Load of Select Foods

A complete list of the glycemic index (GI) and glycemic load (GL) of all tested foods is beyond the scope of this book—it would be a book in itself. Therefore, we have selected the most common foods. This listing provides a general sense of what are high and low GL foods. We have listed the items by food groups, from low to high GLs. Some food groups are not listed. For example, nuts, seeds, fish, poultry, and meats are not listed—they have little impact on blood sugar levels because they are low in carbohydrates.

For a more complete listing, visit www.mendosa.com, a free website operated by medical writer Rick Mendosa.

TABLE A6-1 **Low- to High-Glycemic Foods by Food Groups**

FOOD	GLYCEMIC INDEX	CARBOHYDRATES (g)	FIBER (g)	GLYCEMIC LOAD
Beans (legumes)				
Soybeans, cooked, 1/2 cup, 100 g	14	12	7	1.6
Peas, green, fresh, frozen, boiled, 1/2 cup, 80 g	48	5	2	2
White navy beans, boiled, 1/2 cup, 90 g	38	11	6	4.2
Kidney beans, boiled, 1/2 cup, 90 g	27	18	7.3	4.8
Peas, split, yellow, boiled, 1/2 cup, 90 g	32	16	4.7	5.1
Lentils, 1/2 cup, 100 g	28	19	3.7	5.3
Lima beans, baby, 1/2 cup cooked, 85 g	32	17	4.5	5.4
Black beans, canned, 1/2 cup, 95 g	45	15	7	5.7
Pinto beans, canned, 1/2 cup, 95 g	45	13	6.7	5.8
Chickpeas, canned, drained, 1/2 cup, 95 g	42	15	5	63
Kidney beans, canned and drained, 1/2 cup, 95 g	52	13	7.3	6.7
Broad beans, frozen, boiled, 1/2 cup, 80 g	79	9	6	7.1
Peas, dried, boiled, 1/2 cup, 70 g	22	4	4.7	8
Baked beans, canned in tomato sauce, 1/2 cup, 120 g	48	21	8.8	10
Black-eyed peas, soaked, boiled, 1/2 cup, 120 g	42	24	5	10
Bread				
Multigrain, unsweetened, 1 slice, 30 g	43	9	1.4	4
Oat bran and honey loaf, 1 slice, 40 g	31	14	1.5	4.5
Sourdough, rye, 1 slice, 30 g	48	12	0.4	6
Stoneground whole wheat, 1 slice, 30 g	53	11	1.4	6
Wonder, enriched white bread, 1 slice, 20 g	73	10	0.4	7
Sourdough, wheat, 1 slice, 30 g	54	14	0.4	7.5
Pumpernickel, 1 slice, 60 g	41	21	0.5	8.6
Whole wheat, 1 slice, 35 g	69	14	1.4	9.6
Healthy Choice, hearty 7-grain, 1 slice, 38 g	56	18	1.4	10
White (wheat flour), 1 slice, 30 g	70	15	0.4	10.5
Healthy Choice, 100% whole grain, 1 slice, 38 g	62	18	1.4	11
Gluten-free multigrain, 1 slice, 35 g	79	15	1.8	12
French baguette, 30 g	95	15	0.4	14
Hamburger bun, 1 prepacked bun, 50 g	61	24	0.5	15
Rye, 1 slice, 50 g	65	23	0.4	15
Light rye, 1 slice, 50 g	68	23	0.4	16
Dark rye, black, 1 slice, 50 g	76	21	0.4	16
Croissant, 1, 50 g	67	27	0.2	18
Kaiser roll, 1 roll, 50 g	73	25	0.4	18
Pita, 1 piece, 65 g	57	38	0.4	22
Bagel, 1, 70 g	72	35	0.4	25

Yogurt, with fruit, 200 g	26	30	0	8
Yogurt, low fat, 200 g	33	26	0	8.5

APPENDIX 7

Hydrochloric Acid Supplementation: Patient Instructions

PURPOSE

The purpose of this self-test is to estimate the amount of supplemental hydrochloric acid (HCl) you need to reestablish adequate stomach acid. Adequate stomach acid is critical for initiating digestion and protecting the intestinal tract from microbial pathogens.

DIRECTIONS

1. Begin by taking one HCl capsule (500 to 600 mg) at your next large meal. At every meal after that of the same size, take one more capsule (one capsule at the next meal, two at the meal after that, then three at the next meal, and so on).
2. Continue to increase the dose until you reach seven capsules or you feel a warmth in your stomach, whichever occurs first. A feeling of warmth in the stomach means that you have taken too many capsules for a meal of that size. Take one fewer capsule the next time. However, it is a good idea to try the larger dose again at another meal to make sure that it was the HCl that caused the warmth and not something else.
3. After you have determined the largest dose that you can take at your large meals without feeling any warmth, maintain that dose at all meals of similar size. Take fewer capsules with smaller meals.
4. When taking several capsules, it is best to take them throughout the meal rather than all at once.
5. As your stomach begins to regain the ability to produce the amount of HCl needed to properly digest your food, you will notice the warm feeling again. This is the time to start decreasing the dose level.
6. Every 3 days, decrease the dose by one capsule per meal. If the warmth continues, decrease more rapidly. If maldigestion symptoms return, add capsules back until digestion improves again.

APPENDIX 8 | The Optimal Health Food Pyramid

The Optimal Health Food Pyramid, shown in Figure A8-1, incorporates the best from two of the most healthful diets ever studied—the traditional Mediterranean diet and the traditional Asian diet. In addition, the Optimal Health Food Pyramid more clearly defines what the healthy components within the categories are and stresses the importance of vegetable oils and regular fish consumption as part of a healthful diet (Table A8-1).

FOODS TO AVOID ENTIRELY

- Refined white flour products: pastas, cakes, muffins, pretzels, etc.
- Refined sugar–loaded cereals, candies, baked goods, etc.
- Processed foods packed full of empty calories (sugar and fat) or salt (e.g., soups, theater-style popcorn, chips, etc.)
- Margarine, butter, and shortening
- Smoked or cured meats: bacon, hot dogs, smoked luncheon meats, sausages, ham, spam, etc.
- Meats cooked at extremely high temperatures or cooked to well done
- Heavily sweetened or artificially sweetened soft drinks, Kool-Aid, juice-flavored drinks, etc.
- Fried foods, including French fries, potato chips, corn chips, and doughnuts

VEGETABLES: FIVE TO SEVEN SERVINGS DAILY

In Latin, the word vegetable means "to enliven or animate." Vegetables give us life and should be the main focus of any health-promoting diet. Vegetables provide the broadest range of nutrients of any food class. They are rich sources of vitamins, minerals, carbohydrates, and protein. Vegetables also provide high quantities of anticancer phytochemicals.

It is very important not to overcook vegetables. Overcooking not only results in loss of important nutrients, but it also alters the flavor of the vegetable. Light steaming, baking, and quick stir frying are the best ways to cook vegetables. Do not boil vegetables unless you are making soup, because much of the nutrients will leach into the water. If fresh vegetables are not available, frozen vegetables are preferred over their canned counterparts. The only exception is tomato products (e.g., soup, paste, sauce, etc.), especially when they also contain oil; canned tomato products actually provide more absorbable lycopene than raw tomatoes.

We have divided vegetable intake into three categories: green leafy and cruciferous vegetables, low-glycemic vegetables, and starchy vegetables. This approach encourages eating a variety of these life-giving foods, helps achieve a "rainbow assortment" in the diet, and enables a focus on low-glycemic choices.

One serving of vegetables equals any of the following:

- 1 cup raw leafy vegetables (such as lettuce or spinach)
- 1/2 cup raw nonleafy vegetables
- 1/2 cup cooked vegetables or fresh vegetable juice

Box A8-1 offers easy tips to increase the daily intake of fruits and vegetables.

Green Leafy and Cruciferous Vegetables: Two to Four Servings Daily

- Alfalfa sprouts
- Beet greens
- Bok choy
- Broccoli
- Brussels sprouts
- Cabbage
- Cauliflower
- Chard
- Chinese cabbage
- Collard greens
- Dandelion
- Endive
- Escarole
- Kale
- Lettuce (the darker, the better)
- Mustard greens
- Parsley
- Spinach
- Turnip greens
- Watercress

Low-Glycemic Vegetables: Two to Three Servings Daily

- Artichoke (one medium)
- Asparagus
- Bean sprouts
- Bell peppers

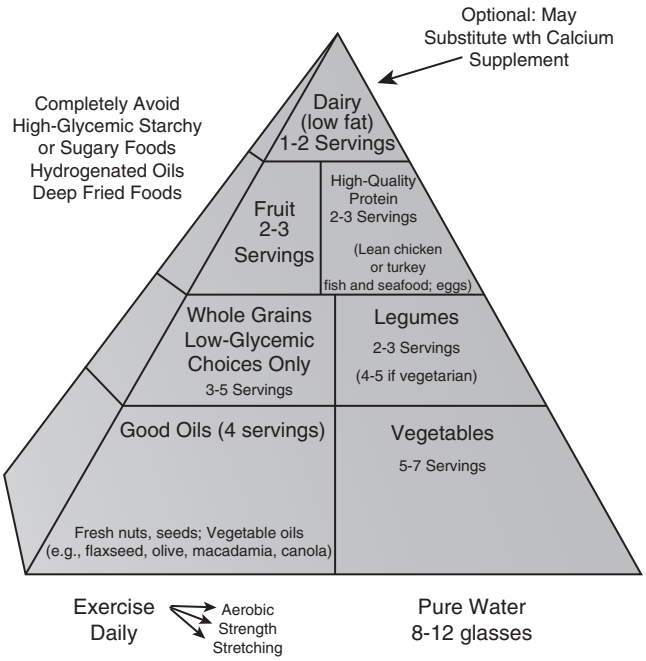

FIGURE A8-1 The Optimal Health Food Pyramid.

TABLE A8-1 **Daily Food Group Recommendations for a 2000-calorie Diet**

FOOD	NUMBER OF SERVINGS
Vegetables:	
Total servings	5-7
Green leafy and cruciferous vegetables	2-4
Low-glycemic vegetables	2-3
Other vegetables	1-2
Good Oils:	
Total servings	4
Nuts and seeds	1
Olive, macadamia, flaxseed, or canola oil	2-3
Whole grains	3-5
Legumes	2-3 (4-5 if vegetarian)
High-quality protein	2-3
Fruit	2-3
Dairy	1-2 (optional)

- Carrots
- Celery
- Cucumber
- Fennel
- Mushrooms
- Okra
- Onions
- Peas (fresh or frozen)
- Radishes
- Rhubarb
- String beans, green or yellow
- Summer squash
- Tomatoes, tomato paste, tomato sauce, tomato juice, vegetable juice cocktail
- Zucchini

Starchy Vegetables: One to Two Servings Daily

- Beets
- Parsnip
- Potato
- Pumpkin
- Rhubarb
- Rutabaga
- Winter, acorn, or butternut squash
- Yam or sweet potato

NUTS, SEEDS, AND GOOD OILS: FOUR SERVINGS DAILY

Nuts and seeds provide the beneficial oils, especially the monounsaturated and medium-chain fatty acids. Regular consumption of nuts has been shown to improve blood sugar regulation and lower the risk for diabetes, heart disease, obesity, and cancer. Focus on raw nuts and seeds. Definitely avoid nuts and seeds roasted in oils or coated with sugar. Nuts and seeds make excellent additions to salads and sautéed greens. Try to eat a variety of nuts and seeds, such as almonds, Brazil nuts, walnuts, pecans, flaxseeds, sunflower seeds, and pumpkin seeds.

Use olive, macadamia, flaxseed, or canola oil both in salad dressings and to replace butter, margarine, and the shortening used for cooking. Never cook with flaxseed oil; it is too rich in polyunsaturated fats, which are easily damaged by heat. Coconut and macadamia nut oils are the best cooking oils because of their ability to remain stable during high temperatures, but olive oil is a good choice for sautéed vegetables, and canola oil is usually best for baked goods because it has the mildest flavor. Coconut oil is also very stable in cooking and is fine to use in small quantities; it contains saturated fat but is metabolized differently from animal-derived saturated fats and can be used safely in moderation. Avoid using safflower, sunflower, soy, and corn oils because they contain too much omega-6 fatty acid (as discussed in Chapter 44).

We recommend at least one serving of nuts or seeds (one serving equals 1/4 cup) and 3 tbsp of the healthy oils daily. In addition, we recommend taking a high-quality fish oil supplement.

BOX A8-1 **Easy Tips to Increase the Daily Intake of Fruits and Vegetables**

- Buy many kinds of fruits and vegetables when grocery shopping, so plenty of choices are available.
- Stock up on frozen vegetables for easy cooking so that a vegetable dish can easily be served with every dinner.
- Use the fruits and vegetables that go bad quickly (peaches, asparagus) first. Save hardier varieties (apples, acorn squash) or frozen goods for later in the week.
- Keep fruits and vegetables where they are easily and frequently seen. The more often they are seen, the more likely they are to be eaten.
- Keep a bowl of cut-up vegetables on the top shelf of the refrigerator.
- Make a big tossed salad with several kinds of greens, cherry tomatoes, cut-up carrots, red pepper, broccoli, scallions, and sprouts. Refrigerate in a large glass bowl with an air-tight lid, so a delicious mixed salad will be ready to enjoy for several days.
- Keep a fruit bowl on your kitchen counter, table, or desk at work.
- Treat yourself to a fruit sundae: top a bowl full of your favorite cut-up fruits with vanilla yogurt, shredded coconut, and a handful of nuts.
- Pack a piece of fruit or some cut-up vegetables in your briefcase or backpack; carry moist towelettes for easy clean up.
- Add fruits and vegetables to lunch by having them in soup or salad or cutting them up to eat raw.
- Use thinly sliced pears or apples in omelets.
- At dinner, serve steamed or microwaved vegetables.
- Increase portions when serving vegetables. One easy way of doing so is by adding fresh greens such as Swiss chard, collards, or beet greens to stir-fry dishes.
- Serve fresh fruit for dessert. Add visual and taste appeal by serving with nuts, cheese, or yogurt. For example, serve grapes or sliced apple with cheese, or a fruit parfait made with low-fat yogurt or topped with berries.
- Add extra varieties of vegetables to soups, sauces, and casseroles (for example, add grated carrots and zucchinis to spaghetti sauce).
- Take advantage of salad bars, which offer ready-to-eat raw vegetables and fruits and prepared salads made with fruits and vegetables.
- Use vegetable-based sauces, such as marinara sauce, and juices, such as low-sodium vegetable juice (V-8) or tomato juice.
- Freeze lots of blueberries and grapes, to use as summer replacements for ice cream, popsicles, and other sugary foods.

WHOLE GRAINS: THREE TO FIVE SERVINGS DAILY

It is very important to choose whole-grain products (e.g., whole-grain breads, whole-grain flour products, brown rice) over their

TABLE A8-2 **Single Servings of Whole Grains**

Bread: whole wheat, rye, or other whole grain	1 slice
Cereals: whole grain	1/2 cup
Corn:	
Cooked whole kernel corn	1/2 cup
Corn on the cob	1 small
Flour and flour products:	
Whole-wheat flour (uncooked)	2-1/2 tbsp
Whole-grain pasta (cooked)	1/2 cup
Whole grains (cooked): rice, oats, wheat, barley, quinoa, spelt, etc.	1/2 cup

processed counterparts (white bread, white flour products, white rice, etc.). Whole grains provide substantially more nutrients and health-promoting properties. Whole grains are a major source of complex carbohydrates, dietary fiber, magnesium and other minerals, and B vitamins. The content and quality of the protein in whole grains are also greater than in refined grains. Diets rich in whole grains have been shown to be helpful in both the prevention and treatment of diabetes, heart disease, and cancer.

Table A8-2 defines servings of various whole grains.

BEANS (LEGUMES): TWO TO THREE SERVINGS DAILY

Beans are a mainstay in most diets of the world and are second only to grains in supplying calories and protein to the world's population. Compared with grains, they supply about the same number of total calories, but usually provide two to four times as much protein, and are a richer source of the soluble fiber that lowers cholesterol and stabilizes blood glucose levels. Although we do not recommend using canned vegetables or fruit, canned beans retain their fiber content and anticancer flavonoids. Plus, given the long preparation time for cooking beans, canned beans are extremely quick and convenient.

A serving size for beans is 1/2 cup.

FRUITS: THREE TO FOUR SERVINGS DAILY

Fruits are a rich source of many beneficial nutrients, and regular fruit consumption has been shown to offer significant protection against chronic degenerative diseases, including cancer, heart disease, cataracts, diabetes, and strokes. Fruits make nutrient-dense, easy between meal snacks and desserts (e.g., nothing could be simpler than phytonutrient-rich fresh berries alone). It is easy to get into the habit of eating only a few varieties of fruit. We encourage eating a "rainbow assortment" of fruits over the course of a week.

A general rule of thumb is that one serving of fruit equals one of the following:

- One medium fruit
- 1/2 cup of small or cut-up fruit
- 4 oz of 100% juice
- 1/4 cup dried fruit

See Box A8-1 for easy tips to increase the daily intake of fruits and vegetables.

HIGH-QUALITY PROTEIN: TWO TO THREE SERVINGS DAILY

The detriment of diets high in saturated fat and cholesterol has been stressed for decades. Likewise, the importance of the omega-3 fatty acids in the battle against development of chronic disease is now also well known. Fish consumption, in particular, has shown tremendous protection against heart disease and cancer. Choose smaller species of fatty fish, such as wild salmon, mackerel, herring, and sardines. Their smaller size and shorter lifespan translate into a lower accumulation of mercury (Box A8-2).

BOX A8-2 **Fish Consumption Caution**

Fish consumption offers significant protection against heart disease and many forms of cancer, especially the major cancers, like those of the lung, colon, breast, and prostate. Although we encourage the eating of more fish, some guidelines are necessary. Nearly all fish contain trace amounts of methyl mercury. In most cases this is of little concern, because the level is so low. The fish most likely to have the lowest level of methyl mercury are salmon (usually nondetectable levels), cod, mackerel, cold water tuna, farm-raised catfish, and herring. However, certain seafood, particularly swordfish, shark, and some other large predatory fish, may contain high levels of methyl mercury. Fish absorb methyl mercury from water and aquatic plants. Larger predatory fish also absorb mercury from their prey. Methyl mercury binds tightly to the proteins in fish tissue, including muscle; cooking does not reduce the mercury content significantly.

We suggest limiting intake to no more than about 2 lb (1 kg) per week. That translates to six 7-oz servings per week maximum. Limit intake of swordfish, shark, and warm water tuna to no more than once a week (or once a month for women of childbearing age who might get pregnant).

We therefore recommend eating fish at least three, but no more than six, times per week. Keep intake of red meat (beef, veal, or lamb) to no more than two servings per month, and choose the leanest cuts possible; keep the portion size limited to about the size of a deck of cards, and do not charbroil or cook the meat until well done, because this practice increases the formation of cancer-causing compounds. Also, consider some of the alternatives to beef, such as venison, buffalo, elk, rabbit, and ostrich; these emerging beef alternatives are lower in saturated fat and provide higher levels of omega-3 fatty acids.

Chicken and turkey can also provide excellent protein with very little fat, especially if only the white meat (breast) without the skin is eaten. Eggs are also a very good source of high-quality protein, and if produced by free-range hens fed flaxseed meal, they will be rich in beneficial omega-3 fatty acids.

One serving equals about the size of a deck of cards; that translates to roughly 4 oz.

DAIRY: ONE OR TWO SERVINGS DAILY (OPTIONAL)

We have found that many people are allergic to milk or lack the enzymes necessary to digest dairy products. Even for people who do tolerate dairy foods, milk consumption should be limited to no more than one or two servings per day. Use nonfat or reduced fat dairy products rather than whole milk varieties. Also, fermented dairy products like yogurt, kefir, and acidophilus-fortified milk are preferred over milk. Some of the soy milk alternatives to cow's milk are delicious, especially when flavored with vanilla or chocolate. If dairy products are not consumed, we recommend a calcium supplement.

One serving of dairy products equals 1 cup of milk, yogurt, or cottage cheese or 1 oz of cheese.

APPENDIX 9

Patient Instructions for Measuring Basal Body Temperature

PURPOSE

Your body temperature reflects your metabolic rate, which is largely determined by hormones secreted by the thyroid gland and by the ability of your cells to convert these hormones to their more active form. Your level of thyroid activity can be determined simply by measuring your basal body temperature. All you need is a high-quality thermometer.

PROCEDURE

1. Place the thermometer by your bed before going to sleep at night. If using a mercury thermometer, shake it down to below 95°F.
2. On waking, place the thermometer in your armpit for a full 10 minutes. It is important to make as little movement as possible. Lying and resting with your eyes closed is best. Do not get up until the 10-minute measurement is completed.
3. After 10 minutes, read and record the temperature and date (a convenient form is printed as Table A9-1).
4. Record the temperature for at least three mornings (preferably at the same time of day) and give the information to your physician. Menstruating women must perform the test on the second, third, and fourth days of menstruation. Men and postmenopausal women can perform the test at any time.

INTERPRETATION

Your basal body temperature should be between 97.6°F and 98.2°F. Low basal body temperatures are quite common and may reflect hypothyroidism. Common signs and symptoms of hypothyroidism are as follows:

- Depression
- Difficulty in losing weight
- Dry skin
- Headaches
- Lethargy or fatigue
- Menstrual problems
- Recurrent infections
- Sensitivity to cold

High basal body temperatures (higher than 98.6°F) are less common but may be evidence of hyperthyroidism. Common signs and symptoms of hyperthyroidism are as follows:

- Bulging eyeballs
- Fast pulse
- Hyperactivity
- Inability to gain weight
- Insomnia
- Irritability
- Menstrual problems
- Nervousness

APPENDIX 10

Rotation Diet Master Chart and Plan

Sally J. Rockwell, PhD, CCN

TABLE A10-1 **Rotation Diet Master Chart and Plan**

FOOD FAMILY	DAY 1 (GREEN)	DAY 2 (YELLOW)	DAY 3 (BLUE)	DAY 4 (RED)
Proteins				
Fin fish	Fish may be eaten daily as long as a different fish is selected each day			
Shellfish	Mussel, escargot, clam	Shrimp	Oysters, scallops, abalone	Crab, squid, octopus
Fowl flesh and eggs	Chicken, goose	Turkey ↔	Cornish game hen, quail, pheasant	Duck
Red meat	Beef (veal, liver, etc.)		Pork (ham, bacon, etc.), lamb	Rabbit
Dairy	Cow (milk, yogurt, cheeses)		Goat (milk, yogurt, cheeses)	
Legumes	Kidney, soy, and lima beans		Pinto, garbanzo, and black beans; black-eyed and split peas	
Sprouts	Nuts, seeds, and legumes	Nuts and seeds	Nuts, seeds, and legumes	Nuts and seeds
Nuts, seeds, and oils	Soy, walnuts	Almonds	Peanuts, pecans, pumpkin seeds	Cashews, pistachios
	Filberts ↔	Pine nuts ↔	Chestnuts ↔	Safflower, corn
	Sesame ↔	Brazil nuts ↔	Macadamias ↔	Avocado ↔
		Sunflower, apricots		Olive ↔
Grains and flours	Buckwheat, soy, quinoa, tofu, arrowroot, guar gum	Rice, millet, rye, potato, flaxseed, xanthan gum	Amaranth, garbanzo, kudzu root, chestnut	Barley oats, wheat, corn, tapioca, agar ↔
Sweeteners	Honey, raisins	Dates, molasses, rice syrup	Figs, currants	Coconut, malt, sago palm, maple syrup
Vegetables				
Beet	Beets, Swiss chard	Carrots, parsley	Spinach	Avocado
Mustard	Cabbage, broccoli, white radish, kale, nappa		Bok choy, red radish, Brussels sprouts, cauliflower	Parsnip, celery
Composite		Leaf and bib lettuce, common artichoke		Iceberg lettuce, romaine
Gourd	Cucumber, winter squash		Summer squash, pumpkin, zucchini	
Lily	Onion, garlic		Chives, leeks, shallots, asparagus	
Nightshade		White potato, peppers	Chestnuts	Tomato, eggplant, peppers
Miscellaneous	String beans	Yams ↔	Peas	Bamboo shoots
		Jicama ↔	Okra ↔	Jerusalem artichoke ↔
		Mushrooms ↔	Olives ↔	Sweet potato ↔
Fruits				
Plum		Plum, prune, apricot		Peach, cherry, nectarine
Apple	Apple		Pear, quince	
Citrus		Lemon, orange, kumquat		Lime, grapefruit, tangerine
Berries	Boysenberry, blackberry, strawberry	Huckleberry, cranberry	Logan berry, raspberry, gooseberry	Blueberry
Gourd	Melons		Cantaloupe, melons	Pomegranate ↔
Miscellaneous	Rhubarb, grapes	Kiwi ↔	Pineapple ↔	Mango, banana ↔
	Papaya ↔	Guava ↔		
	Persimmon ↔			
Bulk	Pectin	Flaxseed ↔	Chia seed ↔	Psyllium seed

All information from The Rotation Game, Copyright 2003. All rights reserved, SJ Rockwell, PhD.

↔, A food that is essentially the only food of a family and that will not cross-react with other foods.

APPENDIX 11 | Supplier Certification Questionnaire Guidance

SUPPLIER CERTIFICATION: COMPLIANCE GUIDE AND QUESTIONNAIRE

This guidance was prepared to assist practitioners in their review of suppliers. To effectively use the supplier certification and quality assurance questionnaires, some background information is needed. The questionnaire asks a series of questions regarding the quality practices and Good Manufacturing Practice (GMP) compliance of the supplier. These questions should be reviewed using a graded approach to determine the level of quality practices the supplier has in place.

In this version of the questionnaire (total of 22 questions), the following questions and their related answers are considered critical, major, or minor points to an appropriate quality system.

Critical Questions: 8, 12, 14A, 15, 18, 19, 20, and 22

Missing answers to the critical questions show potential adulteration and/or contamination problems with materials and/or products supplied. These questions deal with information about the supplier's quality control personnel, specifications, and related testing of raw materials and/or finished products, possible contamination of materials and/or products due to inadequate sanitation practices, inability to substantiate label information, and noncompliance with current food labeling regulations for potential allergens. If the supplier's answers indicate possible contamination and/or adulteration issues with materials and/or products, the use of the supplier should be rejected.

Major Questions: 6, 7, 11, 14B, 16, 17, and 21

Missing answers to the major questions show serious gaps in the supplier's quality program. These gaps include lack of the following: designated quality control personnel, necessary quality procedures, suitable employee training program, adequate internal GMP audit program, suitable review of raw material suppliers, appropriate monitoring of contract laboratories, required testing of raw materials, adequate re-testing of released raw materials, suitable use of expiration dates, appropriate retained samples, and appropriate monitoring and/or verification of subcontracted production. If the supplier's answers indicate possible gaps in the quality program, the number of gaps must be reviewed to determine how much of the quality system is missing or compromised. If the majority of these questions are not answered appropriately, it is recommended these be treated in the same manner as critical issues.

Minor Questions: 1, 2, 3, 4, 5, 9, 10, and 13

Information required by the minor questions should be readily available because it deals with the supplier's name and address, manufacturer's name and address, and contact personnel. The remaining minor questions deal with items that are not mandatory for food producers, such as: GMP audit of the supplier by a third party, written employee training program, frequency of internal GMP audits and how reports are handled, auditing of raw material suppliers, and basis for re-testing of released raw materials.

Any issues surrounding testing of raw materials and/or finished products should be carefully scrutinized. If it appears the supplier is not performing adequate testing and/or examination to provide proof of a material's identity, purity, strength, or composition, the material should be considered suspect and not eligible for use. If they are relying on outside sources for analytic data, it is necessary to ask how they validate the source of that information.

Typically, it only takes one critical issue question to derail use of a supplier, because the questions concern material and/or product contamination and/or adulteration issues. In each situation, after the initial review is completed, the supplier should be notified of the results of the review. Suppliers should be given the opportunity to correct deficiencies and provide proof of the corrections.

Practice Name _____

Address _____

FOREWORD

Our suppliers are the essence of our success. We cannot succeed without quality materials and services. We have therefore embarked on a program designed to develop working partnerships with our valued suppliers. We feel that development of an open, trusting, cooperative relationship with our suppliers is a prerequisite to a meaningful certification process.

Vendor certification is an important component of a total quality management system that assures that a supplier's product is produced, packaged, and shipped under a controlled process that results in consistent conformance to our requirements. It supports the concept of quality at the source by doing it right the first time, thereby substantially reducing or eliminating the need for final quality inspections by the supplier or the customer. The primary objective of the certification process is to assure consistent high quality as demonstrated by predictable conformance to our requirements. The basic premise is that we want to identify suppliers that have adequate process controls in place and they *provide legitimate proof* that their products are consistently fit for use, authentic, meet label claims, and are free from contamination or have maximum freedom from contamination.

It is our goal as a medical practice to offer products that meet or exceed all the applicable regulatory requirements, are clinically effective, and safe for our patients, customers, and friends. We feel very strongly about the importance and need for certification and have included it as a major cornerstone of our business philosophy. We seek to identify and do business with natural product suppliers that attain and maintain full compliance with the proposed U.S. Food and Drug Administration Good Manufacturing Practice guidelines for the manufacture of nutritional supplements currently published in the Federal Register.

OBJECTIVES

We are seeking suppliers who:

a. Are interested in making certification a standard part of doing business and we invite you to join us in our pursuit of excellence. Our suppliers have in place or are willing to put in place a documented quality system.
b. Are committed to partnering with us and developing internal programs to assure consistent quality, good communication, timely delivery, and best overall cost.
c. Have or are willing to put in place a comprehensive Quality Assurance testing program that assures raw material and finished product authenticity, label claim potency, freedom from contamination, and stability over the expiration dating period.

Please answer the questions and return the completed audit to: the address at the top of the form. In an effort to protect your IP and confidentiality, you may provide the first and last sheet only for Standard Operating Procedures, Multipage forms, Audit Reports, etc., as proof of proper documentation.

Please answer each question with Yes, No, N/A, or provide further data.

Corporate and Personnel Information

1. Supplier's name:
2. Supplier's address, telephone/fax number, and web address:
3. Manufacturer's name, address, and telephone number (including all manufacturing sites):
4. Name, address, telephone number, and contact person for any/all of your QA/QC Contract Laboratories:
5. Contact personnel: (provide name and e-mail address)
 Plant Manager:
 QA/QC Manager:
 Purchasing Agent:

GMP and Quality of Procedures Information

Check one column or circle one letter for each.	Y	N	N/A
6. Does the company have a Quality Control Unit?			
7. Does the quality unit have the authority to approve/reject the following:			
a. Procedures	a	a	a
b. Specifications	b	b	b
c. Test methods and results	c	c	c
d. Raw ingredients/components	d	d	d
e. Finished ingredients	e	e	e
f. Packaging materials	f	f	f
g. Labels	g	g	g
h. Processing records	h	h	h
i. Forms	i	i	i
j. Instrument/control calibrations	j	j	j
k. Reprocessing operations	k	k	k
8. Do you have a GMP system in place? If so, which do you follow:			
a. Food GMPs	a	a	
b. FDA GMPs for dietary supplements	b	b	
9. Have you ever been independently certified for GMP compliance?			
If so, by whom?			
a. NPA Date of Last Audit: _____	a	a	
b. NSF Date of Last Audit: _____	b	b	
c. USP Date of Last Audit: _____	c	c	
d. TGA Date of Last Audit: _____	d	d	
e. Other: Date of Last Audit: _____	e	e	
10. If independently certified for GMPs, please provide proof that you successfully passed the GMP audit. (Please attach audit report as proof)			
11. Please provide a copy of: The table of contents for your SOP forms (Please attach)			
12. Do written records exist of employee training and education? If yes, please attach an example.			
13. Does a written GMP training program exist for new and veteran employees?			

Raw Materials

Check one column or circle one letter for each.	Y	N	N/A
14A. If you have an in-house laboratory:			
a. Name/e-mail of supervisor:			
b. How many analysts by level of education are in the laboratory?			
GED____BS____MS____PhD____			

14B. If you use contract laboratory personnel are they audited by:
- a. Company personnel — a
- b. A third party — b
- c. Not audited — c
- d. If audited, how often? Yearly. Every 2 yrs. Every 5 yrs. Other — d

15A. When doing in-house or independent testing of "BOTANICAL" raw materials, are they checked for:
(Please provide two examples of test data for each item, a-g)

- a. Identity (To authenticate material or botanical genus and species) — a — a
 - If yes, are SOME or ALL materials tested? (Circle answer)
 - If yes, how often? (Choose one)
 - 1. Each batch received _____
 - 2. Skip lot testing (If so, how often?) _____
 - 3. Other _____
- b. Microbiology Profile (Bacteria, Yeast, and Mold) — b — b
 - If yes, are SOME or ALL materials tested? (Circle answer)
 - If yes, how often? (Choose one)
 - 1. Each batch received _____
 - 2. Skip lot testing (If so, how often?) _____
 - 3. Other _____
- c. Potency (if potency claim exists) — c — c
 - If yes, are SOME or ALL materials tested? (Circle answer)
 - If yes, how often? (Choose one)
 - 1. Each batch received _____
 - 2. Skip lot testing (If so, how often?) _____
 - 3. Other _____
- d. Heavy Metals (Lead, Mercury, Cadmium, Arsenic) — d — d
 - If yes, are SOME or ALL materials tested? (Circle answer)
 - If yes, how often? (Choose one)
 - 1. Each batch received _____
 - 2. Skip lot testing (If so, how often?) _____
 - 3. Other _____
- e. Chemical Solvent Residue — e — e
 - If yes, are SOME or ALL materials tested? (Circle answer)

Finished Products

Check one column or circle one letter for each.	**Y**	**N**	**N/A**
20. Are your finished products tested for label claim potency before release for sale? If yes, please provide full test data for three different products If not, please provide a rationale for how you prove you meet the label claim.			
21. Do you put expiration dates or a use by date on your products?			
22. Do you do label claim potency testing (Stability Testing) to verify that the product meets the label claim throughout the expiration dating period? If yes, please provide stability potency assays on three different finished product batches that were tested to verify the expiration date claim. If not, please provide a detailed rationale for how you prove that you have met the label claim through the dated period.			

Thank you

APPENDIX 12 | Vaginal Depletion Pack—Traditional Method

INTRODUCTION

The vaginal depletion pack ("vag pack") was originally developed by the eclectic physicians of the nineteenth century and later modified to its present form by John Bastyr, ND. Over the last 50 years, it has been regularly used by most naturopathic physicians in the treatment of various vaginal disorders.

Although no controlled studies of the clinical efficacy of the vag pack have been published, it has a long, and apparently successful, history of use. Its primary application has been in the treatment of cervical erosions, cervical dysplasia, pelvic inflammatory disease, and pelvic congestion. The mode of action is apparently through its local antibacterial, anhydrous, alterative, and sclerotic activities. These are thought to inhibit local microbial growth, stimulate the body to slough off abnormal cervical cells, and promote lymphatic drainage. However, no research has been done to determine the actual mechanism.

Procedure

Supplies

- Open-mouth 1-lb container with tight-sealing lid
- Anhydrous magnesium sulfate ($MgSO_4$; keep tightly closed)
- Glycerin
- *Hydrastis canadensis* tincture: 0.5 oz
- *Thuja occidentalis* oil (not thuja in oil): 0.5 oz
- *Melaleuca alternifoli*a oil: 0.25 oz
- Bitter orange oil: 0.25 oz
- Vita Minerals 120 (iron sulfate solution): 1 oz
- Cotton: 0.5 in thick, 2 in wide, and 3 in long
- Cotton string (surgical grade): 4 in long (dental floss also works well)

Mixing the Solution

The following steps must be followed carefully. Deviation results in either a runny, inconvenient liquid or a rock-hard, unusable precipitate. Each step requires vigorous stirring before proceeding to the next!

1. Fill the container half full with anhydrous $MgSO_4$.
2. Add glycerin until soupy. Mix until the solution begins to cool.
3. Add oils.
4. Add *H. canadensis.*
5. Add Vita Minerals 120.
6. Stir occasionally over the next 2 to 3 hours until the solution cools. It should have a thick, tar-like consistency.
7. Store in a tightly sealed container in a cool, dry place. The solution will require stirring if not used regularly.

The Tampon

The cotton is folded lengthwise and tied at one end to make a tampon 1 in thick and 3 in long, with approximately 3 in of string hanging from the tied end.

Application

The best time for application is during times of normal uterine drainage—right before or after the menses and during ovulation. The procedure is as follows:

1. Fold 1 tbsp of the formula into the untied end of the cotton tampon (some find it easier to put the solution into the cotton tampon before folding and tying it).
2. Expose the cervix with a vaginal speculum and open it wide enough to insert the tampon.
3. Slide the vag pack, formula-end first, through the speculum until it fits tightly against the cervix. (A uterine forceps can be used to hold the pack and aid its insertion.)
4. Carefully remove the speculum while leaving the pack in place. Avoid touching the sides of the vagina because the fresh pack can cause some irritation. The uterine forceps are used to hold the pack in contact with the cervix as the speculum is removed. Ensure that the string is left exposed in the introitus.
5. Leave the pack in for 24 hours, at which time the patient can remove it by simply pulling on the string.
6. Have the patient douche after an additional 24 hours. A mild vinegar solution is recommended.
7. The procedure can be performed weekly until the desired results are obtained.

CLINICAL APPLICATIONS

Typically, the patient notices an increase in drainage, both while the vag pack is in place and during the following 24 to 48 hours. If she experiences any burning or discomfort, the pack can be removed early, followed by douching. Suggest that she wear a sanitary pad to absorb the typical secretions.

Cervical Dysplasia

When the vag pack is used in the treatment of abnormal cervical cells, inspection of the cervix within a few days of the application reveals a red, eroded appearance where the cells have sloughed off. This typically heals within 7 to 10 days.

The number of applications needed varies with the patient and the condition. This is described in the cervical dysplasia chapter (see Chapter 156).
